Generally the same applies to the connectors as to the cable itself - the surplus prices are much lower than the new prices, and larger sizes may even be cheaper.

However, I do agree that you don't need connectors in order to make a splice in a static installation. This technique makes a solid splice, with a low SWR even at 432MHz:

>I have a ham friend who uses long runs of coax to his several towers.

>
And for the smaller sizes with a solid center conductor, splice with a short length of hobby brass tuning over the outside.

>I don't know whether he adds any insulation next or not, but I would
>envision injecting some low-expansion spray foam later.

The foam is mostly empty space anyway, so even at UHF an inch or so will hardly be missed.

>He then wraps the outer conductor with brass or copper foil and solders
>this in place.

In some sizes, a slit length of copper water pipe can work too.

>This is then wrapped with tape for protection. I would use a double
>layer of #27 3M tape with an overwrap of plastic electrical tape.
>
>To strengthen the joint mechanically, he straps on a length of steel
>angle using stainless hose clamps.

Yup, all of the above. It works fine.

The overall conclusion is that - both physically and financially - large hardline is nowhere near as 'hard' as most people think.

BTW, I do have one genuine Andrew splice for LDF5-50, which I'm hoarding for some undefined future need. It's truly a thing of wonder... especially the insert that connects the two hollow center conductors. One end screws in with a tapered variable-pitch thread, so the other end has to have a tapered variable-pitch *left-hand* thread. Only a CNC programmer with far too much time on his hands could have thought of that.

Hardline is hard to beat. (pun intended) Of course, cost and performance
are to be compared.

As another data point: a hardline run of about 400 feet was measured
when installed some 30 years ago (flat on the ground). When making a second
run of the same size hardline over the same path four years ago (Heliax -
part number had changed) both cables were measured for return loss and for
impedance bumps. The two cables were indistinguishable and the measurements
were well within measurement uncertainties from the measurements of 30 years
ago.
The older run was connected to a rotatable 3.8 MHz/3.5 MHz dipole and
the newer run was connected to a large LPDA that starts at 6 MHz on the
basis that surely the older run "should" have more attenuation - though a
difference was not measured.

I echo the point made by Ian about hardline being hard to beat and the
worth (for the runs involved) to find same. Do it right - do it once.

I am shocked to discover that as often as I have used Bury-Flex to
connect things, I have not measured a piece. That needs to go on my list of
things to do! If Roy measured a piece, one can take to the bank what he
measured.

It might be that the BuryFlex is still in use and has not been removed from service as the Heliax you cite has been. After all Davis BuryFlex 9914 does have a warranted - 20 year service life -

Is there any other coax with such a warranty?

Charlie

Before we go much further, is there an engineering data sheet on
Bury-Flex? I couldn't find one on the Davis RF site.

In particular, what is the rated minimum bending radius?

Coaxial cables with braid-over-foil shielding have a generic problem
that if they're bent too sharply, the foil will tear into separated
segments each about an inch long. The cable then relies on the braid for
overall shield continuity. It will still function, especially at low
frequencies, but there isn't much contact pressure to maintain the
continuity between the braid and the foil.

If a cable had been treated in this way, it's not hard to imagine that a
precision measurement at 450MHz would reveal small jumps in the loss and
SWR when the cable is flexed.

But this is NOT something you'd ever notice in a normal amateur station
operation. Even when I was using braid-over-foil coax with 1.5kW at
432MHz, and monitoring the SWR continuously, I never noticed any major
jumps when rotating the antenna. The break-up of the foil only came to
light after the cable had failed for an unrelated reason, and was slit
open for a post-mortem.

Here are my personal experiences and observations with "BuryFlex".

Back in the 90's, I went through a period of station upgrade,
followed by a period of antenna experimentation, mainly with lower
band receiving antennas. To support all of that work I purchased a few
thousand feet of coaxial transmission line, in a wide range of types
and brands.

For my "main" lines, which needed to be buried to make it
from the house, under the lawn, to the "antenna fields", I chose
BuryFlex. I also used it for my single tower, and around the
rotator. The buried runs are approximately 150 and 175 feet long.

For other purposes, such as test antennas that I would
put up for a few weeks, to arrays of those antennas, I would use
BuryFlex, RG-213, RG-8, RG-8X, RG-58, all sort of stuff. I even
had some 75 Ohm RG-11 which was used mainly as "phasing lines"
in delta loop arrays, and series matching sections.

Before all the dust had settled, I had probably installed
well over 100 UHF coax connectors on cables of all sorts of
lengths, from 1 foot to about 250 feet.

Mechanically, I found BuryFlex to be very rugged, and
whenever I have had the opportunity to check out cables in the
field, including buried, they are in excellent condition. It
does have a high degree of flex, and a small turning radius.
Around the rotator, it worked very well, and after a few
years of turning, it showed no signs of wear at all.

As far as attaching coax connectors, I did find that the
stranded center conductor was a little too wide for a few
of the various connectors I would try to use. I tended to
pick up packs of 10 to 25 male connectors at hamfests and
from the Internet, and they probably covered the range of
name brand, strange brand, gold pins, silver pins, Teflon
insulator, and on and on.

I found that about 10% of the range of connectors
I had would not fit over the twisted BuryFlex center conductor.
Initially, I cut two of the stranded center conductors to reduce
the diameter, but as I accumulated a range of connectors,
I just learned which connectors to avoid when putting ends
on BuryFlex.

As part of my antenna experimentation, I would often
be out in the field, right at the antenna, with a typical

antenna analyzer, such as the MFJ-259, 259B, 269, AEA HF-CIA,
and the Autek RF-1. I would then come back inside
the house, where I had a computer next to the radio. I had
a serial interface for the AEA HF-CIA, so I could capture
SWR graphs on the computer, for a whole range of purposes.

At some point, I picked up a laptop computer, which
made it easy to record antenna analyzer output data right in the
field, next to the antenna, before I entered the BuryFlex
runs back to the house.

An ideal lossless 50 Ohm transmission line should repeat
the SWR found at its load end at its input. The impedance will
be transformed as a function of the length of the cable, but
the SWR should remain the same. Of course we don't have
ideal lines out in the field, we have real lines, with loss.
The impact of the loss is to reduce the SWR at the input (station side)
of the line. In many typical HF situations the reduction is
small.

I noticed that when I overlaid the SWR graphs in the
field on top of the SWR graphs made inside the house, they
did not follow the expected relationship, which is to say the same
general shape, with the inside values slightly lower due
to loss on the cable between the two points.

In some cases, the SWR would rise - I admit, it was
a small amount, but that made no sense to me.

I then performed a test which I must confess I
had not done before. I put a 50 Ohm load on the end of a
length of BuryFlex, and a typical antenna analyzer on the other
end, and swept the frequency across the HF range, perhaps
1 to 30 MHz. I expected to see a flat SWR of 1.0, since
I had a 50 Ohm load, 50 Ohm cable, and a 50 Ohm analyzer.

Well, with BuryFlex, the SWR would swing, as a
function of frequency, between 1.0 and a high of 1.3.

By this time, most of the coax I had once used out
in the field had been rolled up, and stored within
some metal cabinets in the garage. I went and grabbed an
armful of assorted cables, from high quality RG-213, to
pretty darn cheap RG-58 that I used in receiving antenna
arrays. All other 50 Ohm cable, when terminated with
a 50 Ohm load, had a flat sweep across the HF range.

So, something about that BuryFlex was different.
I found all of the lengths that I had rolled up, and
all exhibited the same behavior. I did wonder if I
got a "bad batch", but I do believe that I was measuring
across a set of cables that I had purchased over
a period of perhaps 3 years, and I assumed that meant

that I was looking at different batches and runs and
seasons.

I wasn't sure what was going on, and I wasn't going
to replace that buried BuryFlex, but I stopped using more of it,
especially if I was trying to make useful measurements.
The cable obviously "worked", since I had been pumping
1500 watts through it for year, from 160 meters to 6 meters.

As a few more years passed, and I ended up
interested in higher quality impedance measurements,
as part of understanding and building phased vertical
arrays. I accumulated even more impedance measuring
devices, including old Gen-Rad and Boonton boat anchors.
I did end up with an N2PK VNA, which I believe has
near professional/lab accuracy.

A year or so ago, I got curious about this whole
area again, and now that I had some good quality
measurement equipment, I grabbed some different cables
from the cabinet, and put on a 50 Ohm load, and swept
them from 1 to 50 MHz. Now, what I was really
measuring was the complex reflection coefficient, which
could be converted, by formula, to complex impedance,
SWR, return loss, and all sorts of useful quantities.

When I displayed the data on a Smith Chart, an
interesting pattern emerged. The other 50 Ohm cables spiraled
around the 50 Ohm load. A 75 Ohm cable (with a 50 Ohm load)
also showed a spiral, but it was centered higher up the resistance
axis. The BuryFlex, however, had a spiral which was
centered under 50 Ohms.

Now I'm no Smith Chart expert, especially when it
comes to combining data from different Zo cables, but especially
when comparing BuryFlex to other 50 Ohm cables, to 75 Ohm
RG-11, the pattern is pretty clear.

My conclusion was that the BuryFlex I had here had
a characteristic impedance lower than 50 Ohms, perhaps around 45 Ohms.

After the messages in recent days about BuryFlex,
I went out to the shop this morning, and again grabbed two
different rolls of BuryFlex, a few typical 50 Ohm cables,
and some 75 Ohm RG-11. I wanted to see if I could
duplicate the measurements. All of these cables are a few
years old, and some have been used quite a bit. In other
words, I am not trying to work with new cable right off
of a roll.

I got the same results that I had seen in the
past. I captured two Smith Charts showing BuryFlex versus
other 50 Ohm cable, and some 75 Ohm RG-11. The test

scenario is a random length of cable (more than a few
feet, less than 100), with a 50 Ohm load, and a sweep
from 1 MHz to 50 MHz with 100 KHz spacing. If I were
willing to terminate the BuryFlex with a variable noninductive
resistor, I could probably nail down the actual cable
impedance.

I put the two Smith Charts on a web page so that
they could be inspected by all interested parties.
The URL is:

http://www.seed-solutions.com/gregordy/Amateur%20Radio/Experimentation/buryflex.htm

I certainly can be interpreting this data incorrectly,
and please feel free to correct me if you believe that
I've come to the wrong conclusion.

I do not have an opinion about the "loss" of BuryFlex.
I could make return loss measurements, but for those to
have meaning, I would need to unroll the cable, and measure the
length, and since it's 10 degrees F outside, with 18 inches
of snow, and more coming down, I'm not quite that motivated.
My VNA also stops at about 50 MHz, and the frequency first
mentioned was quite a bit higher (400 MHz). The initial report
also talked about loss as a function of coiling and bending,
which can complicate the test scenario.

For me, and my test equipment here, BuryFlex does
not have the characteristics of any other "50 Ohm" cable
I have measured. I believe that my conclusion that it is more
like 45 Ohm cable as opposed to 50 Ohm cable is correct -
again, for the samples I have here. I have found it to be
mechanically excellent and very rugged. Some coax connectors
don't quite fit over the center conductor.

I am quite suspect, however. I encourage
anybody with access to the cable and appropriate test
equipment to confirm the loss measurements, since I trust
the source of the original claim. Because I don't believe the
50 Ohm specification, I guess it's easier for me to believe that
the loss specification is incorrect too.

If you want to know if your cable is like mine - that's
easy - terminate a length with a good quality 50 Ohm resistive load,
and sweep the frequency while watching the SWR. My BuryFlex
bounces up and down.

Granted the fact in their schools, they may just brush over it in
normal curriculums, that still doesn't eliminate him from learning it on his
own or in college.

>>foot is as high as I practically dare do.

>....[snip]....

Be patriotic: erect a 33-foot metal-pipe flagpole WITH pulley and rope.

Set the bottom of the pole on a strong/thick soda-pop or beer bottle
which is restrained to/in the ground somehow
(I've buried a concrete block -- with its holes
vertical -- until its top is even with the ground
surface, put the bottle in one of the holes, and
filled the extra space with dirt),
mount it firmly to (but insulated from) the top of your trailer, and
feed it with coax
(connect the coax shield to a ground rod driven through
the other hole in the concrete block, the coax center
wire to the base of the tower -- I mean flagpole --
and put a 50-100 Kohn resistor across the connection).

It'll work quite well by itself on 40 and 15 meters, and if you use an
"antenna tuner", you should get acceptable results on 20 and 10 meters
(and higher). With an extra inductor at the base, it should give
passable results on 80 and maybe even some results on 160.

Let your neighbors see you driving in several additional ground rods and
laying lots of radials (although I'm usually lazy and just use the wires
to the ground rods) "to extend lightning protection".

Don't forget to fly a flag occasionally! That's part of the disguise.

Since you are considering using ladder-line, you must be thinking a little
about efficiency; wouldn't ChokeBalun-BalancedTuner-ladder-antenna be at
least as good and maybe even better?

I for one am sick and tired of having to worry all the time about who I'm going to offend by what I am saying. I think people need to grow up, lighten up, get a thicker skin, and just get over themselves.

There are so many laws on the books now, that everything we do, in every moment of the day is probably breaking some law and offending some group.

People are different in this world. That's just the way it is.

I'm sorry if your particular race was screwed over 150 years ago, exterminated 60 years ago, or your land was taken away and you were forced to become members of a society you didn't want to be part of.

There comes a time when you just have to let it go.

If you don't like the way things are, just wait a couple hundred years. I'm sure it will all be different, and your particular group will at last be glorified and vindicated.

History has shown that no society/group/country is around for that long anyway.

Rod

Very well done Greg.

Hopefully, in the fullness of time, you will roll all this information into the web page.

I have read articles on issues with control of the foaming of dielectric during manufacture, it seems more difficult to control than all of the aspects of conventional solid PE dielectric line, so it leaves one wondering if that may be the cause of the apparently low Zo (~43 ohms) that you observed. If so, is it a batch to batch variation, variable along the line (although your charts don't suggest that), aging, temperature, migration of the centre conductor on the roll, etc?

Well done OM.

Owen

There are a number of things that can or possibly happen.

When you test coax connectors and termination effects are part
of the system and need to be considered.

I bought 250ft, then tested the 50ft sections I made up for the tower.
All five tested the same at 440mhz and my confidence factor was
good. The test setup was 0.100 Watt RF source, 3DB attenuator,
RLB, cable section, termaline watmeter. All check on spec
and I was doing to verify connectors installed as well. I only tried
one section for bening effects near the end as I was interested in
how it would behave for rotor loops. I saw now ill efects until I
reduced the bend radius to under 4 inches where it developed
a definitate bump that showed on a TDR. Like most foam cored
cables you can overbend it with bad results. The damaged length
was removed (only 4ft) and the cable placed in service.

Expected 2.9db @ 400mhz. But that does not allow for connectors
or measurment setup. Half that should be 1.45db (50ft).

However my testing was at 440mhz. All loss testing I did was
at 440 because small things look bigger there.

To the limits of the attenuators and meter calibration I'd call the
losses including the connectors right where I'd expect 50ft with
PL259s on at least one end would be. I got at 440, greater
than 1.6db but less than 1.8db. The loss was determined by
removing cable and substituting a known attenuators of .2db
steps as that was as fine as I had. Calculated was 1.66db
based on measurements. Allowing for test error and
connectors the there is some range of error. The RLB was
used to verify there were no visible bumps over the 6m, 2m and
420-450mhz range of the source.

The same setup for 50ft or both RG58A/U, RG8X and RG213
gave me 7db(pl259/ug174), 4.6-4.8(pl259/ug175), 2.4-2.6(pl259).
The RG213 was a suprize as I'd expected losses to be lower.
But the results were consistant. Where I give a range in loss
it is because the lower and higher attenuateors used were
either too low or too high meaning the exact result was somewhere
in between. The loss substitution is likely more accurate than
analog meters. Also I tried to minimize the error from adaptors
and cable transitions where needed though te test method tends
to zero them out by substiution.

I did during installation notice one thing over RG213. The 2M antenna
I'd tuned with a length of RG213 showed a higher VSWR when using the
Buryflex. Further tests reveled the losses of the 213 made the SWR
look better than it was. Antenna was readjusted and all was happy.

Good job Greg. Also thanks for the work on the N2PK VNA software.

By inspection of the loss figures for Buryflex on Davis' web site one can note that the loss at lower frequencies is higher than other RG-8 type cables.

Importing their data into Dan's (AC6LA) "bestfit.xls" spreadsheet shows very poor correlation with theoretical k1, k2 coefficients. I'm observing something similar on some RG-142 that I am measuring with my N2PK VNA. The '142 has a silver-coated, copper-plated steel center conductor and I believe that the skin depth encompasses the steel at lower frequencies.

Anyway, that might be a factor, assuming of course, that their data are valid.

Sorry, I'm not the best person to ask. A lot of the other folks here have a lot more experience than I do with applications like yours. Ruggedness and other physical properties can easily be more important than the technical specifications of a cable under idealized conditions, so I'd listen to people who have used cable for an extended period of time in similar circumstances to yours.

As far as loss goes, you're bump up against the laws of physics. Below a few GHz, dielectric loss in common coaxial cables is negligible. The shield has much larger surface area than the center conductor, so the loss ends up being dictated mainly by the diameter of the center conductor -- the larger it is for a given cable Z0, the lower the loss. Assuming a fixed Z0, the only ways you can make the center conductor larger are to increase the cable outer diameter, or reduce the effective dielectric constant of the insulation between center conductor and shield. The effective dielectric constant is reduced by using foamed dielectric coax, or even more by using mainly air dielectric, with a minimal amount of insulation for physical support. Consequently, for a given Z0 and outer diameter, and otherwise similar construction, foamed dielectric cable has less loss than solid dielectric cable, because its center conductor is larger. Mostly-air dielectric cable has less loss yet for the same reason. (In the microwave region, dielectric loss becomes significant, so there's a further loss reduction when the dielectric density is reduced.)

A stranded center conductor or braided shield increase the loss somewhat. It's difficult to find definitive data on just how much, probably because of the number of variables involved, like shield weave tightness and frequency. But the amount of increased loss can be quite significant, judging by the actual loss of typical coax vs. the loss predicted by the assumption of a solid center conductor and perfect shield. Ian, G3SEK just posted a possible explanation of an additional

loss mechanism for aluminum-foil shielded cable like BuryFlex -- tearing of the foil shield due to bending too sharply.

But I think amateurs often get too hung up on small amounts of cable loss. It's admittedly sometimes very important, but not in most cases. Cost, convenience, ease of use, connector type, and physical ruggedness might well be much more important criteria. And again, there are a lot of folks here who have a lot more relevant experience than I do, so you should listen carefully to their advice.

I do fully agree with your last statement.

I noted when I imported Davis' Bury Flex data to tllce that the
regression model correlation coefficient was lower at 0.9918 than most
other data which tends to come in better than 0.997 and mostly 0.998
or better.

One of the reasons that some lines show a very good fit to the model
(eg 5 nines) is that the measurement data was fitted to a model, and
the published figures are from the model, not the original
measurements, and the error in deriving a model from the published
figures is principally caused by rounding of the published figures.

A possible explanation of Greg's observation of low Zo is that the
foam is more dense than intended, increasing C, lowering Zo, and
increasing loss at higher frequencies.

Owen

I've measured a lot of cable over the years, and have found considerable variation of velocity factor from batch to batch of otherwise identical cable from the same manufacturer, as Owen's articles imply. Assuming that the physical dimensions of the cable stay the same, Z0 will also vary with foam density.

The piece of BuryFlex I have measures right at 80% velocity factor, and very close to 50 ohms. I believe I'm within a percent or two on VF, and an ohm for Z0.

I've definitely seen this in RG-174 and some similar diameter 75 ohm cable, at 7 MHz. The problem with those cables is that the center conductor is made of very fine strands of Copperweld. While the fraction of copper relative to the wire diamter is large, the actual copper thickness is small due to the very small diameter wire, allowing current to penetrate into the steel at lower frequencies.

I've also seen the effect in the time domain when using RG-174 type cable but with solid silver-plated Copperweld center conductor. The increased loss at low frequency actually improves the step response somewhat because of the disproportionately higher loss at lower frequency.

Good work, Greg. It's refreshing to see that some people, at least, are still willing and able to do this rather than unquestioningly accept manufacturer's data. Even if the data turn out to be accurate, the process is truly educational.

The varying SWR while terminated with 50 ohms is consistent with the 45 ohm Z0 you observed. My piece of BuryFlex is right at 50 ohms, but I'm not too surprised at this amount of variation given the foamed dielectric. I measured 80% velocity factor, so if our respective measurements are good, the velocity factor of your piece should be around 72%.

Hi.all, and BTW, Happy Holidays! Am attempting to model
a "Cushcrunch" A-627013, yagi and have it all but written,
and modeled what I have of it-- It is a 70 cm, with 6 and 2
meter yagis, the 6 meter horizontally polarized, both the
2 and 70 cm are vertically polarized, on the same boom, ofset
by aprox 1 inch , and the beast is mounted on a mast, 6 inch
from the two meter reflector. This is the first time attempted
modeling a multi band antenna, especially with the mast in the
same plane as the yagi. My question is 2 fold: 1; Given it is
behind the reflector, just how much diff does THAT add to the
pattern of the antenna, and 2; If it does, just HOW LONG an
element would this represent?? The mast length? and for the
small portion of mast, ABOVE the mast clamp?? Just curious
as to the effect it has . Your thoughts , please. Jim NN7K

Looks like the antenna we used for TRC-24's back in the early 70s late 60s
in Co A USASTRATCOM Long Lines Battalion North. - near Seoul Korea.
So its probably VHF .

Roy Lewallen, W7EL, wrote:

>>>I measured 80% velocity factor, so if our respective
>>>measurements are good, the velocity factor of your piece should be
>>>around 72%.

Ok, my curiosity got the best of me, and I decided to
to measure the velocity factor. My VNA software has
a "distance to fault" feature, and I "worked backwards",
which is to say that I measured a length of the
BuryFlex with a tape measure (27' 2"), and adjusted
the VF on the distance to fault tool until I obtained the
same physical length. The far end of the cable was
terminated with an open circuit.

I happened to start with the measurement frequency set
to 1 MHz. Lo and behold, the VF needed to compute the
same physical length was 72%, as you suggested.

My own understanding is that VF should be constant with
respect to frequency, so I decided to vary the test frequency.
I should have left well enough alone.

I picked 1, 2, 4, 8, 16, and 32 MHz. For those frequencies,
I measured the following VFs:

1 MHz = 72%
2 MHz = 73%
4 MHz = 75%
8 MHz = 80%
16 MHz = 79%
32 MHz = 79%

I'm rounding the VF to integer values, since I don't think that any more accuracy
can be claimed in this setup.

Since that result was a little surprising, I grabbed some mini 8 (8X)
that was nearby, about 51.25 feet. The published VF is 78%, and
I measured the following, at the same test frequencies:

1 MHz = 78%
2 MHz = 78%
4 MHz = 79%
8 MHz = 79%
16 MHz = 80%
32 MHz = 80%

With this cable, the VF appeared much more constant across the
1 to 32 MHz range.

Is there an explanation that fits with my measurements?

Greg, W8WWV

If you're modeling it with EZNEC or a similar program, just include the mast in the model as an additional wire. It's probably not practical to include the entire mast at full segmentation, but I'd think that two or three wavelengths would be enough to get an idea of how much effect it's likely to be having. You could model it as several wires, each segmented more coarsely as you get farther from the antenna. Add and remove the mast wire(s) to see what its effect is.

But your asking about for an equivalent element length for the mast makes it sound like you're using some sort of Yagi-specific program. If you are, perhaps someone familiar with the particular program could answer your question.

So now that has been cleared up..the question remains..
Is there any other coax available for amateur use that has a 20 years
service life warranty?

Hi Greg,

You've made a polished report with enough data, excellent graphics,
and concise narrative to closely examine some interesting issues. It
attended those points of batch process, service, variation across
types and time. This and your follow-on VF examination from Roy's
offhand observation have that Ham spirit.

What is more important is that you revealed errors (or aberrant
results) rather than brushing them under the rug. As this thread has
proven by increasing -ahem- testimony, not all specifications prove
out and sometimes those things not specified raise interesting
questions.

One thing I've learned is that a (good) short circuit is a better termination for this kind of measurement than an open circuit. With an open circuit you get fringing which varies with frequency and cable diameter.

If you don't have a decent commercially made short circuit, you can do reasonbly well with a connector and several radial wires from the shell to the center conductor, or better yet a metal disk. Or you could put a male connector on a short piece of coax and short circuit the end of the cable by squeezing the braid into the center and soldering it to the center conductor, taking its length into account for the measurement of course. The object is to minimize the series inductance which would be created with a single-wire or similar connection.

Wes and Ian can probably point you to more possible causes for this measurement result -- they're the real experts on VNA measurements. I'd be very surprised if the VF really varies with frequency -- in theory, it can't, in an ideal coaxial cable.

Most interesting! The cable I've been measuring has been kept in a coil of about 3 feet diameter, but squeezing and handling it has reduced that to probably about a foot or so at times. But I don't recall the coil size when I received the cable, and of course I don't know anything about how it was handled between the manufacturer and delivery to my home. This might be an explanation for the variablility. I did hear from someone else a while back that he'd seen variability in a foil-wrapped cable, but I don't think it was specifically Bury-Flex. I have some RG-58 size cable with the same general construction which doesn't show this variability. But it looks like the stress would be worse on the foil in a larger diameter cable. Also, there seems to be some difference in how the foil is more-or-less bonded to the PE, and that would also play a role in the stress.

I want to keep the piece I've measured intact for the time being, but if I get up the time and interest to do more measurements on another piece of cable, a post mortem might be revealing.

Further, you may not know the manufacturers specifications for minimum
bending radius to preserve operating characteristics.

When I went to the Davis site, I found a table of losses for several
cables including BuryFlex, but it did not state the length. I assumed
that the length was 100' from the losses quoted for some other cables.
The VF (82%) was buried in text, and I found no explicit information
on Zo, mechanical properties, bending restrictions, operating
temperatures etc. Some properties may be implied by description as an
RG8 type cable, but min bending radius is likely to be larger than a
solid dielectric / no foil cable.

Perhaps there is spec sheet there somewhere, it didn't leap out at me!

Since Greg's test setup measured a much more constant VF for the mini-8, it doesn't seem that the open-circuit termination is causing much error (note also that the largest deviation for the BF is at the lowest frequency, where fringing C would have the least effect).

This seems to bring us back to Greg's method of computing "distance to fault" from measurements of R and X at one end. Does that method involve any assumptions about idealized cable behavior that could create an *apparent* change in the computed VF?

Please share it when you get done. It would remove an item from my do
it list. I never was able to adjust the matching section to my
satisfaction when I first got it. I just left it wherever I was in the
process. That was probably around 1980. I recently bought a MFJ 269
and checked it out. The SWR wanders around quite a bit but always
stays below 2:1.

20 year jacket warranty is _not_ a 20 year service life warranty.
From what other posters are measuring, the cable has a close to
zero service life. Roy can certainly measure things properly and
if he says the piece he had was bad then I believe him. I believe
Greg too. There are just too many bad measurements showing up,
done by experienced and competent people, for it to be coincidence.
The cable is bad out of the box in at least some instances. There
is no warranty covering that AFAICS.

Yes, but that really needs either an expensive floated or balanced tuner
or a remotely controlled one. I use an SGC230 in exactly the line up you
suggested.

Most manual unbalanced ATUs will have an RF hot chassis in that configuration
and hand proximity effects will make them very tricky to tune.

Well, this *is* a (somewhat) public forum. If you need to, you can
learn how to remove USENET postings, and not all servers accept removal
postings. (The issues around USENET removal postings can be argued
elsewhere! It _can_ be done, is all I'm saying. Whether it _should_ be
done, or will actually work is another matter.)

As far as "the youth" being present, while I understand your concerns my
feelings are that it is parents who should be thinking about what the
youth are doing online (and USENET is the least of your concerns as a
parent today). Anyway, most young people either swear like sailors
already, or better get used to it quick.

They know about sex, too, so I think it may be best to just move along
on that one.

Your best bet is to add people to your killfile/plonklist if you find
they raise your blood pressure too much.

4572. Presenting D-Dimond1 antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-12 19:31:20 UTC
From: Dimitris <dilkinis@ee.duth.gr>
Message-ID: <1134415880.815042.320270@o13g2000cwo.googlegroups.com>
Source record: 66619

Hi to all

In the line of my theses I have designed an antenna,
which I consider as prototype(?) and named it D-Dimond1.

The antenna was designed, simulated and examined
(and propably will be constructed) for educational reasons mainly
and not only to be practically exploitable.

The operating frequency will be somewhere between 900 and 1300 MHz.
However, the test frequency that I used for my measurements was 1111
MHz.

So, I would be very happy if you could spend some time
to take a look to some of its characteristics:

The following URL shows the geometry of the antenna in the 3D space.
As you can see, it lies at the yoz plane.
As you cannot see, the input source is considered to be
at the starting point of the axes, O.
http://antennas.ee.duth.gr/ooo/dt/05/hli/08/geometry/geo.jpg

The following URL contains a text file with the coordinates of
the antenna's nodes and also the orientation of the current
running through the segments of the anntenna.
Its the input file to the program that I used
to compute the various characteristics.
http://antennas.ee.duth.gr/ooo/dt/05/hli/08/geometry/input.txt

The following URL will clear out the situation a little bit.
http://antennas.ee.duth.gr/ooo/dt/05/hli/07/standing%20wave%20analysis2.gif
It shows the current distribution (which is assumed to be sinusoid)
at the various segments of the antenna, as it results
from the application of the standing wave theory.
The antenna is composed of 7 dipoles lambda/2.
The angle between the 2 dipoles at both of the tops
of the antenna is 60 degrees.

The following URL shows the radiation pattern in 3D space.
http://antennas.ee.duth.gr/ooo/dt/05/hli/11/3d1da1richwire/da.jpg

The following URL shows the comparison of the radiation pattern
at the 3 main planes (xoy, yoz, zox) at cartesian and polar coordinate
systems
between the analytical and the computational method.

http://antennas.ee.duth.gr/ooo/dt/05/hli/16/comparison1richwire11analytical.doc

During the analytical method the antenna considered to be
polygonical and thinwire. The current distribution assumed to be
sinusoidal.
During the computational method I used a program called Richwire and is
based
at the Methods of Moments.

Finally, the following URL shows a series of measurements of various
characteristics
as the antenna is being divided at an increasingly number of segments.

http://antennas.ee.duth.gr/ooo/dt/05/hli/14/totals.txt

The columns of the txt file from the left are representing:
1.Segments, 2.Frequency [MHz], 3.Rinput resistance [O], 4.Xinput
reactance [O],
5.|Z| input impedance's magnitude [O], 6.Input impedance's phase
[degrees],
7.SWR(Zo=50O), 8.SWR(Z0=75O), 9.SWR(Zo=300O), 10.D directivity,
11.D[dB], 12.D [dBd],
13.Front to back ratio (Ef/Eb)

As you may notice the value of input impedance is too high.
therefore, SWR is very increased.
I've added lambda/2 and lambda/4 transmission lines at the source
which were situated perpendicular to antennas plane (at xoy plane)
in order to alter the input impedance's value.
However, the results from both attempts were not satisfying.

I look forward to hear proposals and advices in order to decrease SWR.
Are there any standard transmission lines at the market with Zo
aproximatelly
to my input resistance so I can recalculate SWR with better results?

I ask apologize for any mistakes and for my poor english
as it is not my native language.

Thank you in advance

Dimitris I.

Source record: 66625

It is a free antenna simulation software NEC2 at http://www.nec2.org/
You must be able to model your antenna and much more with it.

Here is an exemple of what this software can do:
http://www.extremetech.com/article2/0,1558,1641191,00.asp

Sorry windose user, I believe in free software. If you want this
software, it is time to try linux. You must have at least 1 free
partition, and the installation process of most of the linux
distributions will install a double boot windows-linux for you.

Best,
Dominique

I did an analysis of my own (with very poor tools) that indicated that the
antenna is resonant at 93.1 percent of the design frequency with an
impedance of very close to 75 ohms resistive.

Not counting the choke balun (coax coiled on an oatmeal box), my
"expensive" balanced tuner consists of a variable capacitor, two
inductors, and two alligator clips. When my antenna configurations
settle down (probably not soon), I may replace the alligator clips
with a two-dec rotary switch. (Of course, if I had two identical
rotary inductors, I wouldn't need the alligator clips!)

I'm not sure either one of us quite has it right. In a model experiment, I set up a short open circuited vertical dipole just above a perfect ground plane, and applied a vertically polarized plane wave from the horizon. Let's call the resulting voltage at the dipole center V1. Then I changed the direction of the plane wave so it was coming from an elevation angle of 45 degrees above the horizon, but with the same amplitude. The dipole voltage was about 0.7 * V1, about what we'd expect from the change in effective aperture of the vertical dipole due to the different arrival elevation angle. But if I tilt the dipole back 45 degrees so it's parallel to the incident E field, the voltage drops to about 0.5 * V1, another 3 dB. I believe this indicates that the field in the vicinity of the dipole is oriented normal to the ground plane, and it has a magnitude that's about 0.7 as great as it is when the same amplitude wave is fired from a horizontal direction. A second check was to tilt it 45 degrees the other way, so its end is pointing directly toward the direction of the impinging wave. The result was again about 0.5 * V1, adding proof that the field in its vicinity is normal to the ground plane and not tilted in the direction of the source. So the antenna aperture is indeed changing as we change the orientation of the

antenna relative to the field in its vicinity. But that's not the same as the orientation of the antenna relative to the direction from which the plane wave originates. (They are of course the same if the ground plane is absent.) The change in antenna output (in this case) when the source direction is changed is due to the fact that the magnitude of the field strength has changed, not because its orientation relative to the antenna has changed.

When the direction of the plane wave is elevated 45 degrees, it has equal horizontally and vertically polarized components. The horizontal components cancel on reflection, while the vertical components reinforce as before. This leaves only the vertical component in the vicinity of the sense dipole, and it's 0.707 * the value when the same amplitude wave is coming in horizontally. The dipole voltage is maximum when it's oriented to be parallel with this field, that is, vertical.

At least I think this is a correct interpretation of what I'm seeing. These effects are all tied in together, and I've spent so long looking at the problem from the transmitting direction that I'm having some trouble getting my thinking turned around. But I'm slowly getting there.

Sorry Dimitris but I have to agree with Richard Clark.

The frequency range from 900 to 1300 MHz is a common frequency for the older mobile phone systems and the DECT cordless phones.

There are currently many available non-patented aerial designs available when one needs an aerial for this frequency range.

You need to declare a number of other parameters except the fact that you managed to create a novel design.

The question is - Why choose this aerial?

Antenna gain?
Directivity?
Sensitivity to ferronous materials in the close vicinity?
Production - is the aerial easy to reproduce?

As the aerial seems to be a balanced design, how sensitive will the to production tolerances and inaccuracies?

Except for these basic questions - it's always nice to see new or different aerial concepts popping up Dimitris - so keep buggering on!

Cheers

Dan Andersson / M0DFI

The important difference is, Fred, that our Royals do not rule the
country... ie they don't make decisions to go to war, put up taxes,
increase the price of fuel, etc. Your president does and over here
most Brits would not agree with his attitude to the Iraq war,
especially as it appears to have a religious justification in his
mind.

I've visited the USA several times over the past few years since the
Iraq business started and I've heard much criticism of your
Republican government. Bush does not have the whole nation behind him
as he likes to think.

Why? "Happy holiday" means have a happy holy day. It came from the time when the only celebrations were the High Holy days of the Catholic church. Nothing PC about it. Unless PC stands for pretty Catholic.

I think he may be using the tradition of defining a person's religion by what his parents' religion was. In other words, xians claim all babies born to xian parents, even though the parents may not even have been particularly religious and were simply born to parents who also were claimed by the xian church. Same with moozlums, any baby unfortunate to be born into that cult is claimed as a member for life.

BTW, I was born to xian parents who also claimed me for their cult and the defining moment in my life was when they coerced me into joining their church at age 13. I haven't been to church since, and share Marilyn Manson's hope that I'll be remembered as the person who brought an end to xianity.

Hail Satan!

"Even though the god in all of these religions is basically the
same, each regards the way chosen by the others as reprehensible,
and to top it all, religionists actually PRAY for one another!
They have scorn for their brothers of the right-hand path because
their religions carry different labels, and somehow this animosity
must be released. What better way than through 'prayer'! What a
simperingly polite way of saying: 'I hate your guts,' is the
thinly disguised device known as praying for your enemy! Praying
for one's own enemy is nothing more than bargain-basement anger,
and of a decidedly shoddy and inferior quality!"

Mr Richard

Thank you for your time and for the copliment.

First of all, I don't have many expectations
from this antenna. Its geometry has been chosen
somehow randomly.

The profit that we wish to gain from all this
is simply to be delighted in the procedure
of designing, simulating, improving and making conclusions
about an antenna.
If the antenna seems to have interesting
characteristics which can bee useful at certain
applications, so much the better.

We are post-graduate electrical engineering students.
Unfortunatelly, where we come from, there is not too much
effort for research and for developing realistic and applicable
technology products inside our universities.
Therefore, we are just trying to do this
mainly for educational purposes.

I am looking forward for your proposals and advices.

Dimitris I.

Peter, you have to understand a subtlety of the USA government. Even though some members of the Congress criticize the President publically for the IRAQ war, the Congress actually controls the war. They pay for it!! The Congressional criticism is simply to posture for votes in the next election.
- - - - -
Reference: US Constitution Article 1, Section 7 Clause 1:

"All Bills for raising Revenue shall originate in the House of Representatives; but the Senate may propose or concur with Amendments as on other Bills."
- - - - -

If the Congress was really interested in bringing the USA troops home all they have to do is stop the funding.

The most powerful person in Washington DC is NOT the President!! It is the Speaker of the House of Representatives. Why? Because ALL SPENDING [$$$$$$] authorizzation MUST initiate in the House of Representatives. The Speaker of the House assigns committee membership. The committees establish and implement policy by how they authorize spending. The full Congress votes on and approves how the money will be spent!

So, IRAQ is NOT Bush's war! It is a USA war. It is bought and paid for by the representatives of the people. And the people are NOT unanimous but are a majority. That disagreement is the basic strength of the USA form of government. I can criticize my government as a political right.

Dear Dan

You are right at all your points.
I have answered to Mr Richard
and I don't want to repeat myself.

However, I can tell you that there wasn't
any preceded and detailed consideration
about certain constraints, requirements or parameters
for the present aerial in order to be used in specific applications.

The aerial was chosen somehow randomly,
just to "investigate" if this thing "plays" and
how it "plays".

However I have to confess -and actually
I am not too proud about this- that our
educational level and our minimal almost non existent
technical and practical experience
concerning telecommunication and wave propogation matters
cannot allow us to bother with such "complicated" issues.

However, we are wandering into this because:
1) we need to apply our theoritical framework and create
something which may not be very important or useful from
practical point of view but maybe will make us feel
somehow satisfied for that we created something real
2) we may like it

Finally,I suppose that it is uninteresting
for you to be concerned with this matter which hasn't
any practical application.
I will comprehend the reasons
if nobody deals with this post.

However, I will continue to give you
new results about this essay and set
new questions.

With regards

Dimitris I.

Mr Dave

Can you mention the process that you followed
(programs that you used, in what frequency, wire's radius,
value for the conductivity etc)
in order to make this analysis?

I am surpised that you've found this value
for the input impedance, which is so different
from the one I calculated.

Finally, can you explain what you mean by
finding 93.1% resonance of the antenna?

Dimitris I.

This is also the purpose of this group.

>I am looking forward for your proposals and advices.

Beginning with a complex shape may introduce too many variables. This
can make it difficult to judge what is important. However, if you
wish to explore along these lines, you should also include a reference
to compare to. Also, you should attempt to make variations to your
design and compare among them as well. Take care to make the
variations small and then progressively larger so changes do not occur
suddenly.

Short of having a machinist build me some, can anyone advise where I might be able to buy this part for a home made antenna project....

I need an addapter that is 3/8" x 24 thread on one end, and a 1/2" tube on the other... to fit over 1/2" fiberglass rod. I can use 3/8" to 5/8" rod diameters to meet this part specs, if necessary.

Stainless steel or brass would be fine.

4625. Classic Dipole Question

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-14 23:52:00 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <s7mdnb4QJ-KBLT3enZ2dnUVZ_tydnZ2d@comcast.com>
Source record: 66671

Hello,

Have just started reading about, and studying antennas.

Simple question regarding the classic dipole for receiving (although I imagine it's exactly the same for transmitting):

Hope I can explain my question clearly:

I understand that If the dipole is fed with coax, one leg is tied to the outer coax shield.

Regarding the end at the radio -

Is the coax shield "always" tied directly to the radio's chassis ground, (which is also earth ground for my set) ?

Or, are the outer and inner coax conductors sometimes fed into an isolation transformer, and therefore the coax shield would not connect directly to the radio chassis ?

Thanks,
B.

>(which is also earth ground for my set) ?

This is almost always the case. The coax shield may also be grounded
at one or more locations between the antenna and the radio chassis
(e.g. where it enters the building), for both RF-grounding and
lightning-safety-grounding reasons.

>Or, are the outer and inner coax conductors sometimes fed into an
>isolation transformer, and therefore the coax shield would not connect
>directly to the radio chassis ?

This can be done (with an isolated "unun" transformer) but it is
rarely done.

The coax shield does not *have* to be tied to one leg of the dipole, a balun could be used to connect the unbalanced transmission line to the approximately balanced load. A balun is a device which accomodates the transition from balanced to unbalanced or vice versa, without significantly disturbing either environment.

If the coax shield is directly connected to one leg of the dipole (and that is often done), the coax doesn't just provide a means for transferring energy from the feed point to the receiver (using the outside of the inner conductor and the inside of the outer conductor), but the outside of the outer conductor is now connected at one end to the dipole leg, and it and everything connected to it forms part of the receiving antenna itself.

The ins and outs of it!

Owen

Buy a long 3/8"x24 bolt, hacksaw off the head, then expoxy some pipe with
1/2" inside diam in over the end. Make sure the part extending into the
pipe is long enough.

Thanks, Irv. Possibly workable for me, but the threaded end needs good RF continuity to the 1/2" tube end, which will be soldered to a helical winding running up the fiberglass rod.

Ed

B. wrote:
"Is the coax shield "always" tied directly to the radio chassis ground,
(which is also earth ground for my set)?"

"Always" may embrace too much. Usually, the coax shield is almost
directly connected to the radio chassis ground.

B already implied that his dipole has a potential problem as its
connection to the grounded inner surface of the coax shield is shared at
this point by connection to the outer surface of the same coax shield.
This inherently unbalnces the load on the inner surfaces of the coax.
The center conductor has only one load, its half of the dipole. The
inner surface of the coax shield has two loads, its half of the dipole
and the outer surface of the coax.. This is fixed by by a balun between
the balanced dipole and the unbalanced coax.

On the other hand, you may have no objection to distortion of the
dipole`s pattern by radiation from the coax exterior. In some cases it
won`t hurt. In other cases it may be beneficial. It is somewhat
unpredictable, but many dipoles are directly fed by coax and are
satisfactory.

Best regards, Richard Harrison, KB5WZI

I modelled it in MMANA (I said poor tools, remember), using the standard
.8mm wires and free space (no ground).

Then I moved the frequency and recalculated the pattern and impedance
until it became resistive at the terminals. That happened at a frequency
93.1% of what the full quarter-wave frequency would have been. And at
that frequency, the impedance was a resistive 75 ohms. In other words,
it resonates lower than the design frequency (hence the lower
resistance).

I started with 900mhz and ended up with 837.9, if I remember. I didn't
save it.

That will work, Cecil. Especially is I run a nut up on it to tighten on
the lug. Thanks.

Ed

PS: Am still looking for the one that antenna manufacturers use, though.

4634. Program GRNDWAV4

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-15 06:32:15 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dnr2lflak1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 66530

It may be recalled I recently reported an error in program GRNDWAV3
which deals with groundwave propagation from a short vertical antenna
versus frequency and type of terrain.

Although the field strength at the receiving site was correctly
computed, the available receiver input power was exactly 6 dB greater
than it should be.

The error was due to a misunderstanding of vertical antenna gain
relative to an isotrope when mounted above a groundplane. It appears
some of the learned text books are unclear on this point.

My immediate problem was eventually sorted out by Roy and proved by
EZNEC-type programs which are not interested in man-made notions about
antenna gain and isotropes.

The faulty program has now been replaced by program GRNDWAV4 which
makes no use of antenna gains at either end of the path. Download it
and delete the older version.

I am grateful to Icelandic radio amateur, Villi, TF3DX for informing
me of the error. He went back to fundamental principles to prove me
wrong. I have no idea what aroused his suspicions and we are not in
contact with each other at present. He said he intended to write a
paper on the subject.

"A short while ago, I explained why your Faraday cage doesn`t separate E and H as you claim."

There are many examples of Faraday screens at work removing the E field while allowing H field coupling. I chose the Faraday sdreens in medium wave broadcasting used to reduce radiation of harmonics of the channel frequency.

More numerous examples abound. These are the Faraday screens used in isolation power transformers between primary and secindary coils to prevent transient high-frequency energy coupling.

My 19th edition of the ARRL Antenna Book contains yet another example on page 14-2 which says:
"Fig 2 - Shielded loop for direction finding.
The ends of the shielding turn are not connected, to prevent shielding the loop from magnetic fields. The shield is effective against electric fields.

Roy, W7EL wrote:
"If the wavelength is >> 1m, the voltage induced in the center of an open-circuited 1m dipole by a 1V/m field is 0.5 volt, not 1 volt."

An open-circuited dipole (has a small gap in its middle) is mot resonnant at a wavelength of 2 meters, but its individual pieces are resonant at a wavelength of 1 meter. At 2 meters, not a wavelength >> 1m, each 0.5 m piece of the half-wavelength, 1 meter long dipole has a high reactance because 0.5 m is too short at a wavelength of 2 meters to be resonant. At longer wavelengths, the reactance rises.. High reactance does not oppose non-existing current in an open-circuit.

I agree the voltage induced in 1/2-meter of wire properly placed within a 1V/m uniform field is 0.5 volt, not 1 volt. The induced voltage in a wire within a uniform field sweeping the wire rises uniformly along the wire. It can be assumed to be the summation of tiny increments of voltage all along the wire. The voltages of the too-short dipole halves add just as two cells in some flashlights add. Their vectors are head to tail. But, current will be limited by radiation and loss resistances of the wires. It will also be limited by reactance in the wires. Open-circuit, 0.5 V + 0.5 V = 1V.

Richard (Harrison),

What is the voltage measured between the bottom end and ground, of a 1 metre high vertical antenna, above a perfect ground, when the vertically-polarised field strength is 1 volt per metre, and antenna height is shorter than a 1/4-wavelength.

Just a number please.

Reg.

As has been explained here many times before, you can not "RF ground" your coax in the sense of connecting it to earth ground. The wavelength of the ground wire prevents a true ground from happening.

You do need a safety ground (for the AC mains) and a "ground" to your radio chassis, but that's all. I put "ground" in quotes because it isn't really connected to earth. The word "common" would be more accurate, but most hams think of their chassis as "ground". So be it, as long as the true condition is understood.

Thanks, Paul. Your reply is appreciated, as Fred mentioned. There actually may be a time next Summer when we might get over there. Sister in Law lives in Prineville. We were in Redmond for that big RV convention this past summer, but didn't spend any time looking around town. I'll keep your callsign/email in case we do get there again this coming year.

I take it you're a machinist? Maybe, after the Holidays, I'll contact you by email and discuss this again... I may be able to email you pictures or drawings of what I'm looking for when I get a chance, to get your opinion on what I'm looking for..

Ed

As a modification to this, since you can stand 1/2 inch thread, how about using a 1/2 inch bolt and brazing or silver soldering some 1/2 inch ID tube over it? Not only will this be easier than trying to center the 3/8 and potentially stronger than epoxy, but it would keep that RF continuity.

This is the sort of part that's expensive to turn out as a one-off part, but very easy to manufacture on an NC lathe -- even a cam-driven automatic screw machine would handle this with ease. Because of this I suspect that there aren't any on the open market; rather a manufacturer would just send drawings to their favorite screw machine place to have them made 10000 at a time.

It's also the sort of part that's fun to make in limited quantity -- it looks pretty, you get to practice your threading, yet its not too critical. So you might want to take up Paul's offer, perhaps with a nice drawing. Just don't ask him to make too many.

I see no tricks in the question. The field strength is given as "1 volt per metre".

From page 23-3 of the 19th edition of the ARRL Antenna Book:
"The standard of measure for field intensities is the voltage developed in a wire that is 1 meter long, expressed as volts per meter."

While field strength is not the same as the volts delivered to a receiver, because of the voltage division between antenna impedance and receiver input impedance, there is no voltage division when the antenna is loaded with an open circuit. We assume the r-f voltmeter used to measure voltage at the base of the antenna has an infinite input impedance. The antenna used for field strength measurements is often a loop, but we are not concerned with the measurement itself. Reg had a very simple question, "What`s the voltage at the base of a 1-meter high wire?

The voltage at the base of an open-circuit 1-metre wire iis one volt because it goes straight to the definition of field intensity in volts/m.

Best regards, Richard Harrison, KB5WZI

> Open-circuit, 0.5 V + 0.5 V = 1V.

There are two incorrect statements here.

First, the voltage induced in the wire doesn't rise uniformly along the wire. It's sinusoidal, even for a very short wire. This is different from the transmitting case but interestingly doesn't interfere with reciprocity.

Secondly, the voltage at the center of an open-circuited 1 meter (electrically short) dipole in and parallel a 1 volt/meter field is 0.5 volt as I said earlier, not 1 volt.

I'll be glad to provide a number of references. Both these statements can also be verified by modeling.

The definition of field strength, incidentally, has nothing to do with the voltage of a dipole immersed in that field.

"Ground" is one of the most misued terms among amateurs that I encounter. Somehow, labeling something "ground" imparts magic properties -- "grounded" things don't radiate, you can't get a shock or rf burn from "grounded" items, "grounded" items are free from the same rules that all other conductors must follow. None are true.

If your rig is mains-powered, you need a mains safety ground, as Bill said. This effectively connects the equipment to the Earth at mains frequency. If lightning is a threat, you also need a lightning ground, which effectively connects your antenna to the Earth when lighning strikes the antenna or nearby. Making an effective safety ground is simple; making a lightning ground is an art and science in itself.

If you have a balanced load for your rig (for example, a coax or twinlead feedline with equal and opposite currents on the two conductors), you don't need a "radio ground", that is, a low impedance connection between your radio and the Earth at radio frequencies. The only time you need one is if you've managed to make your rig a part of the antenna by allowing currents on the outside of a coax feedline, or unbalanced currents on a twinlead feedline. And getting this low impedance connection can be difficult -- or impossible, if multiple frequency bands are involved.

Actually my point was that this is exactly the sort of market where
there _won't_ be a large-scale source, at least not an open one. It's a
market dominated by a few vertically integrated manufacturers, who have
no vested interest in commonality of parts and _do_ get advantages from
having design control over the parts they get. If nothing else it make
it much more expensive for the guy down the road to start up his own
operation.

Consider that nuts and bolts were not truly standardized until around
100 years ago. Before (AFAIK) then manufacturers would specify by size,
but there were no commonly used standards until the SAE got together and
made it happen. As a result nuts and bolts became commodity items and
the price went down.

Hi, Ed.
No, I am not a "machinist". Just hobby that turned into a very useful way to make/build/repair things.

I was a retired computer programmer/systems analyst/data communications consultant. After my partners and I sold the business in Kirkland, WA, my wife and I moved to dry/sunny Central Oregon. Was 4° this morning. 8-10" snow on ground for 2+ weeks. Maybe Puget Sound wasn't so bad after all!

After 1 1/2 years, my wife thought I should find a job. Noting for a guy 60 years old. Saw an ad for a partner in an elctronic assembly business here in Redmond. Bought 45% of the business in 2000. We had one customer. Have built it to $750,000 in sales this year and 7 employees. Partner died a year ago, and the widow gave me the rest of the company in exchange for paying off a note. Hope to do a million next year!

Without the metalworking hobby experience we would have spent many thousands of dollars on tools, tooling and equipment.

I have been working on getting a mobile HF set-up in my pickup truck. Working on mobile mounts for antennas since last summer. Still no decision on how to mount.

So, Ed, can we make contact on 75 meters or 160, or where? We can discuss this some more on the air!

Paul, KD7HB

"Do you have a reference which defines field strength in terms of
voltage induced in a wire?"

Here is more of one I already posted. It is from the 19th edition of the
ARRL Antenna Book on page 23-3:
"The strength of a wave is measured as the voltage between two points
lying on an electric line of force in the plane of the wave front. The
standard of measure for field intensity is the voltage developed in a
wire that is 1 meter long, expressed as volts per meter. (If the wire
were 2 meters long, the voltage developed would be divided by two to
determine the field strength in volts per meter.)"

Best regards, Richard Harrison, KB5WZI

Here is a reference from a professional source. B. Whitfield Griffith, Jr. was Director of Advanced Development at General Dynamics Corporation at Garland, Texas when his book, "Radio-Electronicc Transmission Fundamentals" was published by Mc Graw-Hill in 1972. On page 322, Griffith writes:
"The strength of an electromagnetic wave is generally measured in terms of the intensity of the electric field; this is expressed in volts per meter, or millivolts or microvolts per meter, as the conditions may indicate. This value may be understood as being the numbeer of volts which would be induced in a piece of wire one meter long placed in the field parallel to the electric lines of force; the induction of voltage would result from the movement of the magnetic flux across the wire.

Griffith agrees with Terman.

Understand what you are saying, but this item I am describing is
pretty much standardized, near as I can tell. Soooo many mobile antenna
manufacturers, including CB, use it on their 1/2" fiberglass rod based
antennas, that I am pretty sure there must be a sizable source,
somewhere.

RH> Griffith agrees with Terman.

He clearly contradicts himself in my opinion. He says it "is generally
measured in terms of the intensity of the electric field" then goes
on to talk about induction by magnetic flux. Further, he is not saying
that "it is" but that it "*may* be understood as". He is making an
example of one way to proceed. He is not saying they are the same
thing, only similar. There is a difference not a matter of syntax.

This reminds me of a contradiction I find in Einstein's equivalence
principle. He states accelerating at 1G is the same as being pulled by
the Earth's gravity at 1G. In my opinion, they are similar but they
are not quite the same thing simply because in the former there is
motion and for the latter there is not.

Asimov wrote:
"He clearly contradicts himself in my opinion."

Griffith echoes Terman.

Terman writes on page 2 of his 1955 edition:
"The strength of a radio wave is measured in terms of the voltage stress produced by the electric field of the wave and it is usually expressed in microvolts per meter."

Terman does not literally mean that it is the electric field which is measured. In his handbook Terman says that a magnetic loop antenna is usually the field strenngth meter`s antenna. Terman meant that field strength is quoted in volts per meter. It is irrelevant which field is actually measured as the two fields are locked in magnitude by the impedance of space, 377 ohms. If you know one, you know the other.

Terman also wrote on page 2:
"The strength of the wave measured in terms of microvolts per meter of stress in space is also exactly the same voltage that the magnetic flux of the wave induces in a conductor 1 m long when sweeping across this conductor with the velocity of light."

The electric and magnetic fields serve to recreate each other in their flight from their source. Either could be measured to get the strength of the wave. Neither field directly produces volts in a wire.

As Terman says, it is the wave sweeping the wire at the velocity of light, the d(phi)/dt that generates the volts.

Hello:

Have been reading up on lightning a bit, and it certainly
is a confusing subject.

Let's say I have an Inverted-L or a Sloper in the yard (receiving only).

If a lightning storm is in the vicinity, obviously the best protection
possible is to just disconnect the radio from the antenna. No differences
of opinion here, I would imagine.

But, as a more or less theoretical question, to minimize the possibility of
lightning hitting the antenna at all, or inducing large voltages in it, is
it better to just leave the now "floating" antenna alone, or is it better to
ground one end of it ?

Why ?

Thanks,
B.

>decision on how to mount.

I once mounted a 7-foot-long plain ol' 2x4 on the outside of my pick-up truck's bed on the driver's side with 2-3 angle brackets. This gave me a nice platform for mounting all sorts of whip antennas using no more than an electric drill, some screws & bolts, and a big screwdriver. At one time I had three hamsticks (for three different bands) mounted at the same time, with coax to a selector switch inside next to the radio. Probably wouldn't have worked too well if/when the 2x4 got wet, but for experimentation it was just fine.

Later I mounted a PAIR of hamsticks (for the same band) end-to-end (to make a horizontal dipole pointing fore and aft) on a wooden post which stuck up about two feet above the cab. Worked like a charm! (Think NVIS). Until I drove into the garage and the forward-pointing whip speared the loop in the garage-door pull-down loop!

==========

Frank,

The situation changes by the hour so I suggest you don't spend a great deal of time trying to sort things out. Either the program is in error or you have entered incorrect data. Or (see below) both you and I have the correct answer in the first place.

From the situation at present we have :-

It seems the numerous Bibles written by learned professors don't agree on the subject.

Computer programs, whose results are falsely taken as being gospel truths, don't agree on the subject.

The 'experts' who contribute to this newsgroup can't agree on the subject. But, from the frequency of arguments which result. this is perfectly normal.

I remain as an innocent, neutral bystander, in danger of being unjustly accused of being a troll, whereas -

All I need is an answer to my simple but essentially fundamental and practical question -

"What is the voltage measured between the bottom end of a 1 metre high vertical antenna and ground, when the field strength is 1 volt per metre?"

It goes without saying, a perfect ground is assumed, the antenna height is less than 1/4-wavelength and the radio wave is vertically polarised.

Is the measured voltage 1 volt or is it 0.5 volts?

There's a simple factor of 2 involved somewhere. Should I take a statistical average of the replies if there are any?

What happens on an isolated dipole is irrevalant. It is just a
time-wasting diversion.

I don't have access to the 'learned Bibles' or to computer programs
(except my own). So there is no point in referring to them. But I
don't consider this to be any handicap. Short, logical, convincing
explanations in plain English and perhaps a little arithmetic would be
welcome of course.

Reg, G4FGQ.

As I said, I do not have access to the many ancient, learned volumes about radio transmission and antennas. Or to the many computer programs.

But I do recall mention of "Effective Height" of vertical antennas which has NOT been mentioned in the numerous prolonged threads on this newsgroup about the relationship between receiver input power and field strength.

What "Effective Height" means may be vague. But some sort of a definition may be a clue to solving my problem. Don't mention Marconi, Terman, Kraus, Balani, et al.,

Hmm, I asked a simple question involving your arbitrary use of a
factor of two (2) and you dismissed it as my "anger," or somesuch
clumsy diversion.

Most of your correspondence has been tainted with trolling, what is
different in this case?

Sorry, that is now two (2) simple questions which, no doubt, you will
find undecipherable. Don't worry, we are all capable of observing
that given Richard H. directly responded to your question with a
straight answer - your lack of returning to him puts this troll
squarely at your doorstep.

As for your observation (if it quacks like a troll...):
>Computer programs, whose results are falsely taken as being gospel
>truths, don't agree on the subject.
it seems you are now the author of two (2) such programs that covers
both sides of the argument. I suppose the chance of being 50% right
outweighs the risk of being 100% wrong. ;-)

That, of course, presumes an insecure perspective (which is validated
by having two answers for any question - rather returns us to your
typical trolls, doesn't it?).

Lord Kelvinator is winding up another pitch to wing a chunk of
railroad chalk off your noggin'. Watching you duck throughout these
threads has become an amusing prospect.

Thanx for the entertainment,
Richard Clark, KB7QHC

A contradiction which might only appear if you were to confuse little g and big G. Eistein was referring to the former, which is the acceleration a falling body experiences as a result of the force of gravity on Earth - a change of velocity of 9.8 meters per second in one second. Clearly motion is involved. Big G is the universal gravitational constant, which is in units of Newton meters squared per kilogram squared. Clearly, this relates to a force in Newtons which varies as the square of mass and the inverse square of distance, according to Newton's law of gravitation. Motion is only involved if the force is not met with an equal and opposing force - as is obviously the case when standing on the ground.

Repeating what was previously posted. The following model treats a 1 meter (perfect conductor) monopole, of 0.814 mm diameter, connected to a perfectly conducting ground. I have applied a vertically polarized incident E-field of 1 V/m (peak). The base of the antenna is loaded with the antennas complex conjugate of 1.747 + j823.796. NEC2 computes the current through the load ast 0.2863 Amps (peak), which is 0.5001 V peak. This appears to agree with Reg's program.

Possibly someone can point out if there are any errors in the following code:

```
CM 1 Meter Vertical
CE
GW 1 50 0 0 1 0 0 0 0.000814
GS 0 0 1
GE 1
GN 1
EX 1 1 1 0 90 0 0 1 1 1

Hi,

I've seen here before suggestions about using a tuned loop to increase the gain of radio controlled clocks. Do you think this could also be used to increase the gain of a gps receiver?

I guess that loop should be 1wl circumference, or about 2 1/2 inch diameter, easy enought to cary in a pocket and play with.

I know one can not have more than 0 dB with full omni, I just guess the minimalistic antenna in pocketable gps is way below 0 dB and could maybe be improved a little.

Could this be modeled in EZNEC, one segment with some series resitance for high loss antenna and the other 19 to simulate the loop?

Bill-

That's what I was going to say!

I recall a field day activity where the club was using the press box of a
high school football field, with antennas strung between light poles. As
a storm approached, there were sparks several inches long jumping between
disconnected antenna connectors and nearby grounded equipment. These
sparks were induced by lightning strikes that were some distance away.

Grounding would have eliminated the sparks by providing a metalic path for
the discharge. I doubt it would have had any influence on whether an
antenna would be directly hit, or would have provided any substantial
protection in the event of a direct strike.

Traditional wisdom is that having tall trees nearby, as well as tall
objects such as light poles, will shield you from lightning. But there
are no guarantees. And lightning doesn't always strike the top of tower!

Interesting. Assuming a plane wave sweeping broadside, with the field being the same at every point along the wire, one might be inclined to argue that the voltage induced on a wire should be the same at every point along a finite length. The "rise" in voltage as the field sweeps past would be with respect to time, rather than with respect to position. Sort of explains why a radio receiver works just fine with only one wire attached when you think about it. ;-)

One might, if it were an exceptionally short piece of wire. Otherwise
it must exhibit some greater reactance than nearly 0 and support a
difference of potential in proportion to the current through it. There
is also the radiation (non-0) resistance to consider (same observation
of a potential difference there too).

Presumably, this all hinges on what is meant, in practical terms, for
"finite length."

>The "rise" in voltage as the field sweeps
>past would be with respect to time,
With respect to what time? The time for the wave to sweep past? What
frequency? The full wave, or its peak? or its average (0)?

>rather than with respect to position.

Position of what?

If we could generate a step-wave, and that wave impinges upon the wire
broadside, and we were to arbitrarily assign the frequency of 3 MHz
(so that the wire length of 1 Meter is one percent long - a short
antenna by any definition); then the first degree would immediately
demand a response in 1nS. 1nS is a very appreciable dT for 1 Meter's
worth of inductance.

Still and all, 1nS is hardly the slice of the wave an antenna wire
sees, unless it is 1nS thick - or 33cm. This comes close to a tower's
size, but receivers work with far thinner stuff and the dV/dT
certainly pushes the voltage drop across 1 meter of that wire up
higher.

You have to think carefully about what you are trying to protect.

It seems to me that in the event of a lightning stroke in the near vicinity of your antenna, large voltages will be induced in the antenna wrt "ground", whether or not your antenna or its support structure features as a streamer, or takes the current from a leader.

That voltage may be sufficient for insulation breakdown, and charge will flow to ground via some path, not necessarily of your choosing. Substantial physical damage may occur where insulation breaks down, the path of the side-flash current may result in further damage to persons or equipment.

If you make a substantial connection from the feedline to some thing, you have some degree of control over the path that the discharge current flows. Properly chosen and implemented, that might be better than doing nothing, but if poorly designed or implemented, it could be worse than doing nothing. Side-flash can still occur where you have provided a path to ground.

Very often, the target of effective lighting protection of radio installations is minimisation of voltage drops or potential differences internal to an installation as a result of lightning discharge current rather than trying to minimise the voltage to "ground" resulting from the current.

You seem to be arguing that the induced potential in the wire is due to IR or IZ. I don't think that's true. According to JC Maxwell, the magnitude of the induced voltage and current should depend on the EM field and on the in situ permitivity and permeability of the wire. As long as those things are constant along the length of that wire, there is no reason to expect anything but uniform voltage and current along the length of the wire. As Roy said, an antenna does not behave the same on receive as it does on transmit apparently. A receive antenna does not appear to behave like a transmission line.

> Presumably, this all hinges on what is meant, in practical terms, for
> "finite length."

Finite here just means small compared to any curvature of the wave front. Were the wire long enough compared to the distance to the source, one couldn't expect the fields to be uniform along the length of the wire.

>>The "rise" in voltage as the field sweeps

It just means voltage as a function of time - like the waveform induced by the fields of a passing electromagnetic wave for example.

>>rather than with respect to position.
>

>
> Position of what?

It means position along the wire - as in the topic of the conversation
you've joined.

I apologize for any lack of clarity on my part.

Source record: 66479

This thread has presented a clear illustration of the danger of quoting from a book, even an authoritative one, without fully understanding the context.

Before I continue, let me stipulate that the conductors being talked about here are all electrically short (much shorter than a wavelength), and are placed parallel to the E field. The following statements won't be generally true if both those conditions aren't met.

I've been saying that the voltage at the center of an open circuited 1 m dipole immersed in a 1 V/m field is 0.5 volts. Richard has quoted some references which say that the voltage induced in a 1 m wire immersed in a 1 V/m field is 1 volt, and implying that it follows that the voltage at the center of an open circuited dipole of that length is 1 volt. It isn't, and I'll try to explain why.

The voltage drop, or emf, across a very short conductor in a field of E volts/meter is E*L volts, where L is the length of the very short conductor in meters. This is undoubtedly the reason for the statements like the ones Richard has quoted. If we look at the emf generated across each tiny part of a one meter long dipole by a 1 V/m field and add them up, we'll find that they total 1 volt. But what's the voltage across the dipole, from end to end? The answer to that is it's just about anything we want it to be. Any time we try to measure the voltage between two points in space when there's a time-varying H field present, the answer we get depends on the path we take between the two points. Crudely but not entirely accurately put, it depends on how we arrange the voltmeter leads. We can, however, measure the voltage at the dipole center, across a gap that's arbitrarily small.

So what's that voltage? I can't think of any line of reasoning which would deduce that it's equal to the total emf along the wire (1 volt for our example). You can casually open various texts and find the answer to that -- it's either 0.5 volts, as I've said, or 1 volt, as Richard has said. To understand the reason for the apparent contradiction requires digging more deeply into the texts.

Most of the texts I have analyze field-conductor interactions with a special kind of dipole which has a uniform current distribution -- that is, the current is the same amplitude all along the dipole's length. There are a couple of ways you can physically make a dipole like this. One is to begin with a conventional (but short) dipole and add large end hats, like a two-ended top loaded vertical. A number of authors (e.g., Kraus) show a diagram of such a dipole. Another way to get a distribution like this is to stipulate that the dipole really be only a tiny segment of a longer wire. The short conductor with uniform current

is often called a "Hertzian dipole", sometimes an "elemental dipole", sometimes just a short or infinitesimal dipole, or by Terman, a "doublet". As Balanis (_Antenna Theory - Analysis and Design_, p. 109) says, "Although a constant current distribution is not realizable, it is a mathematical quantity that is used to represent actual current distributions of antennas that have been incremented into many small lengths." The voltage at the center of a one meter antenna of this type in a 1 V/m field is 1 volt.

But this fictitious dipole, used for conceptual and computational convenience, isn't a real dipole. A real dipole -- that is, just a single, straight wire with a source or load at its center and no end hats -- doesn't have a uniform current distribution. Instead, the current is greatest in the center, dropping to zero at the ends. When transmitting, the current on a short dipole drops nearly linearly from the center to the ends. When receiving, the current distribution is nearly sinusoidal. The net result of this non-uniform current is that the voltage at the center is less than it is for a uniform-current dipole -- exactly half as much, actually. Conceptually, it's because the current near the ends contributes less to the voltage at the center. I'm going to wave my hands over the significance of the different receiving and transmitting current distributions, except to say that reciprocity is still satisfied in all ways, including the transmitting and receiving impedances being the same. To add confusion, the gain, directivity, and effective apertures of both types of dipole are the same -- 1.5, 1.5, and 3 * lambda^2 / (8 * pi) respectively. This means that you can extract the same amount of power from an impinging wave with either type of antenna, provided that you terminate each in the complex conjugate of its transmitting feedpoint impedance. The radiation resistance of the uniform-current dipole is 4 times that of the conventional dipole. (Remember, these are all electrically short.)

There's a common term for the relationship between the field strength and the length of a conductor, called the "effective height" or "effective length". The voltage at the center of a dipole in a field of E volts/m is simply E * the effective length. The concept is valid for any length conductor, not just short ones. The effective length of a uniform-current dipole is equal to the wire length. The effective length of a short conventional dipole is 0.5 times the wire length. The effective length for receiving is the same as the effective length for transmitting -- in transmitting, it relates the strength of the field produced to the *voltage* -- not power -- applied across the feedpoint. If you apply 0.5 volts to a standard dipole and 1.0 volts to a uniform-current dipole, the power applied to each will be the same because of the 1:4 ratio of radiation resistance, and the generated fields will be the same. This is consistent with the antenna gains being the same.

As I mentioned, most text authors use a uniform-current dipole for analysis. One which directly derives the voltage of a standard short dipole is King, Mimno, and Wing, _Transmission Lines, Antennas, and Wave

Guides_. Many others, including Kraus, _Antennas_ (2nd Ed. p. 41), derive the effective length for a short conventional dipole as 0.5 * the physical length, from which the open circuit voltage due to an impinging field can easily be determined.

As a last note on a point of contention, electric field strength is usually defined not by the voltage induced in a conductor but from the force between charges using the Lorenz force law. The unit of electric field strength is found to be newtons/coulomb, which is the same as volts/meter. Among the texts using this definition are Kraus (_Electromagnetics_), Terman (_Radio Engineering_), Ida, Majid, and Ramo et al.

You've specified a plane wave of 1 V/m peak arriving in a horizontal direction over a ground plane. This results in a field strength of 2 V/m peak at the antenna. For more information about this, look at my postings over the last couple of weeks on the thread "Antenna reception theory".

A friend is giving me a Rohn-Loc tower climbing safety cable system. It's a 3/8-inch cable that is suspended from the top of the tower to the bottom. It's kept about 6 inches from the tower face and held under tension. The climber has a "Safety clamp" attached from his climbing belt to the cable. The generic name for this is a cable grip.

I need the "Safety clamp" (cable grip) to complete the system. Does anyone know where to get one of these? I just need the grip, not a complete belt. If you have one of these set up on your tower I'd like to know if you like it.

No. If you were to increase the gain of your GPS antenna, either by redesign of the antenna or by an external parasitic structure of some sort, it would have to result in a narrower pattern. So you'd reduce the reception in some directions.

> I guess that loop should be 1wl circumference, or about 2 1/2 inch

0 dB relative to what?

Once you get the desired coverage angle, the only way to improve the reception of the GPS is to improve the receiver signal/noise ratio. The only way you can do that from outside the GPS is to use an external antenna with a preamp having a lower noise figure than the GPS's receiver.

> Could this be modeled in EZNEC, one segment with some series resitance
> for high loss antenna and the other 19 to simulate the loop?

I'm not sure what the "high loss antenna" is. If you mean the GPS antenna, it's not high loss at all, but is likely very efficient. If it's a patch antenna, you can't model it at all with EZNEC. But even if it's a quadrifilar helix, you can't model it with one segment.

Reg, G4FGQ wrote:
"What do photons have to do with winning a contest?"

I don`t know. But, B.Whitfield Griffith, Jr. has some observations in "Rado-Eledtronic Transmission Fundamentals" that may be a useful check on your computations. I expect he checked, rechecked, then checked again before publication. He put a transmitter on an elemental antenna but it would work the same in reverse. From page 325:

"An Elemental Antenna

Since the length of an antenna is commonly expressed in electrical degrees and since this allows the convenient use of trigonometric tables in computing the ratios of currents in various parts of an antenna, let us choose as our elemental antenna a piece of wire which is 1-degree in length and in which the current is constant from one end to the other.We shall first assume that this elemental antenna is located far out in space, so that its field is not disturbed by reflections from the surface of the earth or from any other object. This, of course, is a most improbable set of conditions, but we can certainly imagine that we have a situation such as this and compute from the field equations its electromagnetic result.

These computations will show, first of all, that the maximum field intensity will be produced in the directions which are at right angles to the direction of current flow. This is a reasonable result, since the magnetic field which is produced by the current surrounds the wire in concentric rings and thus gives rise to a radiation field which moves outward at right angles to the wire. As a matter of fact, the field intensity, measured according to our standard procedure at a distance of 1 mile in any direction from the radiating element, will be found to be proportional to the sine of the angle between the direction of the current flow and the direction in which the measurement is taken. If we represent the field intensity at 1 mile in any direction by the length of a vector starting at the center of the element and extending in that direction, the tips of the vectors will mark out the radiation pattern of the antenna element. A cross section of the entire radiation pattern of this element is shown in Fig. 39-2; the entire pattern would be obtained by rotating the figure about the axis of the antenna element.

But this pattern tells us only the relative signal strength in various directions; it is a normalized pattern, with the intensity in the direction of maximum radiation being considered simply as unity. We need much more information than this; we must know the relationship between the current and the actual value of the field it produces. Further computation from the field equations gives this relalationship; we find

that a current of 1 amp flowing in the antnna element will produce a field intensity of 0.3253 mv/m at a distance of 1 mile iin the direction of maximum radiation. We have said nothing about the frequency, and we do not need to; as long as the wavelength is shorter than 1 mile, so that there are no serious induction-ffield effects to upset our calculations, this figure will be correct at any frequencyfor which the length of the element is 1/360 wavelength.

The field intensity of the elemental antenna is directly proportional to the current. Therefore, if the current in the element is 15 amp, the field intensity will be 15 X 0.3253, or 4.8795, mv/m at 1 mile. Similarly, the field intensity is directly proportional to the length of the element; an element which is 2-degrees in length, carrying a current of 1 amp, will thus produce a maximum field intensity of 0.6506 mv/m at 1 mile.

Best regards, Richard Harrison, KB5WZI

I always tell new Hams to ground everything they can.... but if they get a direct hit then they will be too busy fighting fire to worry about the antenna...

A short dipole antenna with 1 amp of current at the center has an
average of 0.5 amp of current along the whole length. So it should be
obvious from the above analysis that the field from a dipole is half the
field from the elemental antenna with uniform current which the author
is discussing. Or, instead of just taking the average, you can integrate
I * delta L to get the same result.

I bought a Gap Titan a few years ago because it is a vertical dipole.
It has been a satisfactory antenna. It is noticably quieter than a
1/4 vertical and there's no need for the ground screen neccessary to
make a 1/4 wave vertical work.

I have it mounted in my back yard on a pipe driven into the ground. It
is about three feet off the ground.

It's pretty much worthless on 75M and marginal on 40M. On 20M and up
it does OK. Depending on the time of year, it performs better than
the W5GI I have at 40 ft. I prefer it to any of the 1/4 wave
verticals I have used.

Heh heh. This can also be beneficial... I was slightly involved with
this a few years ago:

"Raytheonï¿½s Anti-jam GPS Receiver (AGR) supports the Tactical Tomahawk
missile program. The AGR is a PPS (i.e., Y-code) GPS receiver that
operates on both the L1 and L2 frequencies. When configured with a
multi-element Controlled Reception Pattern Antenna (CRPA), the AGRï¿½s
post-correlation nulling techniques allow continued satellite track in
the presence of high levels of hostile jamming.

The AGRï¿½s patented approach to anti-jam also implements satellite beam
steering, to further enhance the tracking thresholds, and to mitigate
the ï¿½spurious nullsï¿½ that can degrade the performance of other nulling
implementations (e.g., pre-correlation).

The AGR sequentially tracks up to eight visible satellites, and
provides high-quality pseudorange/delta pseudorange (PR/DPR)
measurements corrected for the effects of selective availability. The
Tactical Tomahawkï¿½s navigation processor then uses the PR/DR
measurements to yield a high-performance navigation solution."

Hi,

I was thinking about why radio wave communications are not generally used underwater. Basically I'm asking what are the quantitative components of the underwater medium that makes it impractical except for perhaps very short ranges. Things like attenuation, impedance, etc... Does any one here know these details or have them handy?

The conductivity of water causes great attenuation at all but very low frequencies. Think "skin effect".

That having been said, the US Navy (and probably all other folks with subs) use extremely low frequency RF (30kHz IIRC) to communicate with strategic nuclear subs.

I picked up a used one last sprng, set it up about 3 ft off the ground in the back yard...and took it back down within a couple of weeks.
Signals were way down compared to my 450 ohm ladder line fed 80 meter doublet on all bands.
I remade the Titian into a 40 ft vertical dipole that I use on 40 thru 10 meters, fed with twin lead, and much better results.

I had the same experience with a 1/4WL 40m vertical. Now I wish
I had run some A/B transmitting tests as well as the A/B
receiving tests which the vertical flunked mainly due to an
extremely high noise level. I'm thinking about putting the
vertical back up as a 1/4WL 30m vertical fed at the base with
an SGC-230 that I already have. Such an antenna should work
pretty well on 40m-10m, at least for transmitting.

This summer my 80 foot tower took a direct hit, the first in my 48
years of hamming. The tower was grounded and there was no fire, but it
tripped a circuit breaker in my house and damaged a radio connected to
it. My point is that fire is not an automatic consequence.

Incidentally, the sound of thunder from a hit that close is remarkably
different from a hit some distance away. First, you hear the clap from
the nearest part of the bolt and then from parts successively farther
away, a long, rolling sound that continues much longer than one at a
distance. If I don't ever hear it again, that will be ok by me. :-)

Hi Cecil....let us know if you do that. When I redid the back yard lawn, I installed an extensive buried radial system for such experimentation. I have all the aluminum tubing left over from the Titian's tuning stubbs to turn my 40 ft vertical dipole into something wth some capacity hats...to get it to work on 80 thru 20 meters, if I desire.

Bill;

Ain't been there, Ain't done that, Don't want no stinkin t-shirt. ;^)

Seriously though glad that nothing really serious happened. When I was
in retain sales I sold many electronic items to people that suffered
both direct and indirect hits. Lots of damage no injuries everyone was
lucky.

Long years ago, 50 yearsor so before I reached Ham status, a thunderstorm awakened me in the wee hours and proceeded to dance around in the shallow hill pasture near the house. Stroke after stroke occurred and all so near I could hear a loud click as the strike occurred and then the diminishing rumble. I still haven't figured out the initial click sound, it came from outside so wasn't a house internal electric phenomenon.

Penetration of water by radio waves is directly proportional to
wavelength. The longer the wave length the further the penetration of
water. That's why the Navy uses extremely long wave length signals to
contact deep submergence subs. Even then it takes a very long time to
transmit a very short three or four letter message. Of course the sub
then has to raise up to just below the surface and extend an antenna
mast to contact the COMNAVSAT for its full message.

The attenuation of a radio signal through water is staggeringly high except at extremely low frequencies. Fresh water is lossy for two reasons: one is that the polar molecules attempt to align themselves with the oscillating electric field. This physical motion results in loss. The other is that "fresh" water generally has dissolved salts which increase its conductivity. Salt water's loss is dominated simply by its conductivity.

Here are a few numbers for attenuation per meter. It's hard to find good data on loss in real fresh water, but I did locate a representative number for one frequency.

F MHz Fresh water Salt water
0.01 3.9 dB
0.1 12
1 39
10 121
100 ~ 50 dB 369

>"ground" resulting from the current.

I should have expanded that to say:

Minimisation of potential differences is often obtained by one or more
of:
- providing an alternate low impedance path to ground so that less
current flows through the equipment room;
- single point earthing to reduce the voltage drop in earthing
conductors internal to the equipment room;
- equipotential bonding to reduce the voltage drop between the
equipment room earth and other parts of the building, and other
services or structures (eg water, gas, telephone, power).

There may be standards or codes that apply to lighting protection in
your area, they are worth checking, and while they may not mandate
lighting protection, they may mandate the way in which it is done if
it is done. That may have implications for your insurance.

Effective lightning protection is a very expensive business, and if
you don't need "continuous operation" and have a simple configuration,
it is much cheaper and effective to ensure that feedlines and similar
conductors (like rotator cables) are totally disconnected from the
shack at times of high risk.

I've read that this click is due to the ear's reaction to the strong electromagnetic pulse. If that's what you heard, it comes from the ear itself, not from outside.

This is the first time I have seen it mentioned the ear reacting to the electromagnetic pulse. Most of the time it is described as the same way the old WW2 depth charges sounded in the submarines. YOu get the click and then the boom. I forgot the term used but it is something like an impulse or pressure shock wave traveling faster than the speed of sound and then the actual sound wave.

I've read that this click is due to the ear's reaction to the strong
electromagnetic pulse. If that's what you heard, it comes from the ear
itself, not from outside.....

According to old Gary Coffman posts, he says it's picked up by the
auditory nerve. Also, deaf people can hear that click.
I've had two strikes to my mast with me sitting 15 ft away from the
base of the mast. I could hear that click, but I also could hear
the arc sound of the strike going to ground outside. Sounded
like a light bulb being thrown to the ground outside my window.
Not that loud really. I'm fairly convinced the quality of the ground
connection effects the loudness of the strike. The strikes that hit
my well grounded mast are fairly quiet, not counting the overhead
sonic boom. The strikes to the trees in the yard are super loud
in comparison. A loud crack, instead of the quieter arc sound.

But, as a more or less theoretical question, to minimize the
possibility of
lightning hitting the antenna at all, or inducing large voltages in it,
is
it better to just leave the now "floating" antenna alone, or is it
better to
ground one end of it ?

Why ?.....

I prefer to ground all the feedlines. I have a ground strip outside
my window with a bunch of SO-239's. I just screw em all in when
bad wx is around. I doubt it will make much difference as to the
likelyhood of being struck. Horizontal wire antennas are not struck
that often compared to verticals, trees, etc.
But if it is, I'd prefer it to be grounded to reduce flashing, etc.
My metal mast takes the brunt of the strikes to ground. All
my grounding of the feedline does is take any left over energy
on the coax to ground. Same for induced energy from near
strikes. And it can be a good bit, as I actually can hear my
connectors arc with nearby strikes. Never leave antenna wires,
or feedline ends in the house, or in bottles, etc..You want it
out of the house if it's not protected. Even if using a grounded
switch, etc, I'd prefer not to have it running through the house.
IE: ground wire leading along the wall, etc to the switch to
ground it. Most switches ground the unused connectors, or
have a ground position. I don't like those in the house if the
feed is unprotected by gas tubes, etc...

Thanks OM, I've wondered for nearly 50 years what the "click"
mechanism was. I've told the story several times, but never to anyone
I thought it would be useful to ask for an explanation of the "click".

I do believe that any mechanical wave, such as a pressure or shock wave, travels at the speed of sound, no more and no less. To travel faster, it would have to be an electromagnetic wave.

Reg, G4FGQ wrote:
"Just a number please."

Given 1 volt per m as the field strength, and a 1-m antenna parallel to the electric vector of the wave, the open-circuit voltage at the end of the wire is 1 volt. The best you can get across the receiver input is 0.5 volt when there is a conjugate match between the receiver and the antennna.

Most of the explanations are irrelevant when the field strength is specified at the antenna.

Terman preached scientific gospel. He had proof to back what he said. In Terman`s 1943 "Radio Engineers` Handbook" he wrote:

"The strength of a radio wave is expressed in terms of the voltage stress produced in space by the electric field of the wave, and is usually expressed in either millivolts or microvolts stress per meter. The stress expressed this way is exactly the same voltage that the magnetic flux of the wave induces in a conductor one meter long when rhe wave sweeps across the conductor with the velocity of light." This is found on page 770.

There is no qualification or equivocation. Terman also posts the same statement with no change in substance on page 2 of his 1955 edition of "Electronic and Radio Engineerinng". It means what it plainly says.

Best regards, Richard Harrison, KB5WZI

I can no longer resist the urge....

As with most things: it depends.

The whole antenna world knows that a short, thin, uniform metal rod that is normal to a conducting plane has an open circuit voltage at its base that is equal to one half of the size of the incident vertically polarized E field multiplied by the rod's length. Such an antenna has a "height" that is one half of its physical length.

Note: open circuit voltage
Note: short - less than 0.1 WL
Note: the current distribution of the subject rod tapers linearly to zero at the distant end of the rod
Note: the voltage or power delivered to something other than an open circuit is not discussed
Note: many references that discuss short rods are assuming a constant current along the rod's length - such rods have a "height" equal to their physical length

I have dealt with approximations of the subject device. In each case, an extremely high input impedance amplifying device is placed at the base of the antenna that has a known voltage amplification and a 50 ohm output impedance. Knowing that a close approximation of the open circuit voltage is amplified by a known amount, a calibrated, tuned voltmeter (at 50 ohms) is able to measure the size of vertically polarized E (with the usual uncertainties). (and a bit of arithmetic)

Thanks for the info. I had read that submarines communicated in a
band of a few 10's of Hz because of the problems with water. As for
the polar molecules aligning themselves, this implies it takes some
time to achieve. Thus there is a resonnant point in this and if there
is resonnance then there might be anti-resonnance too. Might you know
where this natural molecular resonnance is? Might this be the standard
microwave oven frequency?

Richard (Harrison)

I'm sorry Richard, you have not anwered my question. I will repeat it.

"What is the voltage measured between the bottom end and ground of a
1metre high vertical antenna when the field strength is 1 volt per
metre?"

Assume a perfect ground and antenna height is much less than
1/4-wavelength.

A measured voltage is always relative to or is between TWO specified
points.

Hi Mac,

I too, will jump in with alternatives to this short, thin rod feeding
an infinite Z. It makes for a simple specification, but when the
frequency begins to climb such is not very practical. Input Z's tend
to be dominated with strays and that "short" rod begins to become
enormous. Such artifacts of the MF era are quickly discarded.

The NIST methods (NIST technical note numbers 1309 and 1098) employ
resonant sized dipoles feeding a DC Hi R (and hence AC Hi Z load) at
the gap of the elements. By DC Hi R, the detector filter employs
50KOhm components in a balanced cascading filter that in turn feeds a
Hi R voltmeter through 250KOhm leads (carbon impregnated plastic
conductors to decouple both loading and induction).

Uncertainty, worst case, is 1dB.

Schelkunoff's algorithm is used to find the length of the dipole (no
real surprise here for halfwave length). The effective length is not
half, but rather closer to 62 - 63%.

Relative to what? The other terminal has to be extremely close to the end of the wire in order for the voltage to be single valued.

The best you can get across the receiver input is
> 0.5 volt when there is a conjugate match between the receiver and the

Sorry, that's not just a little wrong, it's wrong by orders of magnitude. For example, a 1 meter long 10 mm diameter dipole, terminated in the complex conjugate of its self impedance (load Z = 0.8855 + j6030 ohms), in a 1 V/m field, has about 1667 volts across the load. Hardly a half volt!

The BW is a product of the information bit rate and the fundamental
frequency. Water enters the picture to drive the fundamental
frequency.

>As for the polar molecules aligning themselves, this implies it takes some
>time to achieve.

Displacement time by ionic polarization can be as short as s/10ï¿½ï¿½

>Thus there is a resonnant point in this and if there
>is resonnance then there might be anti-resonnance too. Might you know
>where this natural molecular resonnance is? Might this be the standard
>microwave oven frequency?

For water? salt water? at what temperature? Ice, whose relaxation
time can vary one order of magnitude for each 10ï¿½C, is considerably
different from water. Its conductivity plunges like a rock with
temperature too (at roughly the same rate) to become a nearly perfect
dielectric.

The relaxation time for Ice runs in the kilohertz whereas for water it
is in the high gigahertz (and has nothing to do with the microwave
oven frequency as simple heating shifts this relaxation time one order
of magnitude between freezing and boiling). Yes, 6 orders of
magnitude change when going from 0ï¿½ ice to 0ï¿½ water.

Attenuation figures may follow this post.

For the casual reader, I should emphasize that this analysis, like all the others on this thread, assumes zero loss. The conditions I described could never be achieved in real life because of unavoidable loss. But it's important to first understand how a lossless system behaves before we add the complicating factor of loss.

Hi Roy,

Thanks for the answer. Please don't think I'm trying to be "smart",
just curious about these things and not knowledeable enough.

Roy Lewallen wrote:

When talking about loop antennas people talk about "capture area".
Whatever that is, this seems to be what makes a ferrite bar antenna
more sensitive than the equivalent simple coil tuned to the same freq.
I know that by using a ferrite bar you are narrowing the pattern, but
I'd think that the main gain does not come from the pattern narrowing
but from "capture area increase" (again, please bear with my ignorance,
these are only my thoughts on what I've read on the Web)

An isotropic antenna; AFAIK a perfect isotropic antenna would have 0 dB
gain

Please let me doubt that. For a given coverage angle you can't make
better than a perfect antenna, but you can certainly make worst (think
of a T2FD).

I dont know how efficient they are, but I do know that normal commercial patch antennas are noticeably less efficient than helical ones, and then, for the helicals, I doubt that something aprox 1/10 wl is anything close to efficient. If this was to be true I'd love to build an equivalent 6.5 ft. helix to work on 20m!

Looks to me like you are confusing "efficiency" with "directionality". That is, a small loop, or a short dipole, will have a low radiation resistance, and when it's small or short enough, the resistance in the conductors of the antenna becomes appreciable compared with the radiation resistance. That causes a loss of efficiency, because the signal energy ends up heating the wire resistance instead of being useful to the receiver. But a helix and a half-wave dipole will both be very nearly 100% efficient. The difference is that the helix is quite directional.

One way to get better reception would be to have a set of highly directional antennas (high gain antennas) that track a set of the visible satellites. Do you really want to do that? Or do you perhaps instead want an antenna that has a pattern that "sees" better in a cone with maybe a 25-40 degree elevation above the horizon, because the satellites directly overhead are not generally the problem? As is commonly the case, you should probably consider the whole system, not just one part of it. What, exactly, is the goal?

Cheers,
Tom

Not sure I really understand what is going on, but have been aware of your
previous postings, also on the NEC-list. What I should have said is that
the above program agrees with Reg's previous assumption -- but not with his
new program "grndwav4.exe". In any case, just to satisfy my curiosity, I
ran the following code, which is, in essence, almost identical to your
NEC-list post with 5.555.... kW input producing 1V/m peak at 1000m. The
following agrees exactly with Reg's new program.

CM Short Monopoles
CE

```
GW 1 50 0 0 1 0 0 0 0.000814
GW 2 50 1000 0 1 1000 0 0 0.000814
GS 0 0 1
GE 1
GN 1
EX 0 1 50 00 65698.12106 0.00000
LD 4 2 50 50 1.747 823.796
FR 0 3 0 0 19.9 0.1
RP 1 1 360 0000 0 0 1.00000 1.00000 1000
RP 0 181 1 1000 -90 45 1 1
EN
```

Noting the comments by others, obviously familiar with ATR measurement techniques, this exercise with NEC is purely academic. There is no way you could experimentally prove these results. Since I have never made measurements on an "Open-air" test site it will be interesting to verify Mac's assumptions, which I am sure are correct.

The confusions I have are now related to the fact that NEC results depend on how the incident E-field is generated. I will check all previous posting by Roy to see if I can figure out this anomaly. For some reason I have not received any update concerning the NEC list postings.

Frank

West-

I've heard third-hand about one Ham Engineer who was having trouble
getting a Gap to perform to specs. After discussing it with the company,
he decided they misrepresent the antenna and is in the process of filing a
class-action suit against them. I couldn't find any information via
Google.

I do believe that any mechanical wave, such as a pressure or shock
wave,
travels at the speed of sound, no more and no less. To travel faster,
it
would have to be an electromagnetic wave.

Also, the deaf person wouldn't hear the mechanical wave. Well,
unless they had "some" hearing still available. If it was proven that
a totally deaf person could hear it, that would pretty much nail it
down as
electromagnetic. If that came out to be true, then Coffmans theory
about the auditory nerve picking it up would probably be true unless
some other nerve was actually involved.

It is noticably quieter than a
1/4 vertical .....

Note...A red flag should always go up when noise is reduced
vs another antenna of the same basic type. :/
Worthless on 75m? If this is late at night when a vertical
"should " do well, I'd be concerned.
Myself, I've never been much of a fan of gap verticals.
But...I'll leave it at that.. I like regular ole full size verticals
in general. Only my mobile uses a stunted vertical.. :/
BTW..If the vertical is not a complete antenna, as in halfwave,
it needs a groundscreen no matter where on the radiator the
antenna is fed, if it's ground mounted. Even a half wave is
improved when ground mounted. Note that most BC stations
that run 1/2 waves, use 1/2 wave radial screens under them.

Dear Richard:
I am obliged to you for your useful comments.
In the large TEM cells that I use to about 200 MHz (with care above about 150 MHz) a very small probe is inserted through the roof of the cell. That probe is used, with the sort of processing you mentioned, to provide one verification of the E inside of the cell. (The other verification comes from measuring the power going in and coming out of the cell, and the internal dimensions.) The probe-scheme's success is helped by the fact that E can go up to 200 v/m (or more) so a lot of signal is available.

Interesting things happen to some electronic equipment well before 200 v/m. A TEM cell with a spectrum analyzer can inform about what a device is radiating.

Still, outdoors, a one meter rod over a large ground screen placed well clear of other structures provides the means to measure (with reasonable uncertainties) the low TOA vertical E field up to 20 or so MHz.

A scheme that I saw at NBS circa 1975 (now NIST) to measure an estimate of total field uses orthogonal, very small doublets with diodes at their center. They received a patent on the idea. To bring the DC to a measuring device, lossy transmission lines were used so as to make the transmission lines "invisible" to the field. In other words, the step up from rod-and-screen is a big step.

In my youth, I measured VHF signals propagated by FM broadcast stations in the "hills" of West Va. to enhance the VHF propagation models that then existed. The purpose was to be able to predict interference to a radio astronomy site. We used tuned dipoles elevated some standard distance that I do not remember.

As many here have said: It is not easy to measure fields.

A few years ago I was out fishing at my favorite pond. It had clouded
over, but had not yet begun to rain. All of a sudden I could feel myself
beginning to tingle, it seems to me it was more in the feet, there was
a sour taste in my mouth, and then all of a sudden a bolt from the blue
hit the pond not far from where I was standing -- scared the living heck
out of me. The buildup of the tingling was a matter of a few seconds,
then the bolt, so I still don't have full recollection of just where the
bolt hit. I jumped back and
landed on my butt, but other than that there was no damage. I quickly
gathered my gear (not trusting the statistic that it wouldn't hit twice
in the same place) and headed for the car. I sat in the car and watched
the pond to see if any fish came to the surface to see what happened but
no such luck! This was in the foothills of the rockies and I got quite a
light show till the storm passed over!

4744. PAR EFL-SWL Antenna, & Inverted L Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-18 17:53:55 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <TdadnXV54pSyPzjeRVn-sg@comcast.com>
Source record: 66441

Hello:

Pretty much a beginner with this, but have been putting a fair amount of time into
trying to understand antenna radiation patterns. Guess I finally have to admit that I'm 3d challenged, and
frankly have difficulty in visualizing them.

So, let me just ask:

Am thinking of purchasing a PAR EFL- SWL receive only antenna for my attic. Can probably be considered as an end fed dipole
Will probably run it as an inverted L, with the vertical section being about 10 feet, and going from the attic to the floor below where the radio is. As the total length is 45', this would leave 35 feet going horizontally.
(placing outside would not be practical)

Interested in as omni as possible, as do listening most anywhere from 0.5 to 30 MHz.

Have two questions, please:

a. anyone ever use this antenna ? Think it would be "substantially" better than what I have now which is a simle random length wire going around the 4 sides of my attic. Would sure appreciate any thoughts and opinions on his PAR unit.

b. How "omni" is it ?

e.g.,

If I have the wire axis running N-S, is most of the sensitivity then in the E-W direction (perpendicular to the wire) ?

If so, will I pick up "anything" in the N-S direction ?

Thanks,
Bob

> useful to the receiver.

No, I was not confussing it. When I talk about "efficiency" I amb
refering exactly to that, to radiated energy vs. energy lost heating
the wire.

> But a helix and a half-wave dipole will both be very nearly 100%
> efficient.

There are many classes of helix antennas, and all the "normal" helix
antennas you will find have dimensions comparable to a full wl if not
greater.

My doubting on pocketable GPSs antenna's efficiency is based merely on
their size. They are about 1/10 wl long. The only other antennas of
comparable size I know are loops, isotrons, fractals, CFA, EH and CB
sticks and, except for tuned loops, we know how they are treated
whenever they appear in this forum.

> The difference is that the helix is quite directional.

The ones used in GPS receivers are exactly the opposite. They should
ideally have a "half orange" radiation pattern, as they should be able
to follow a satellite from horizon to horizon all over your head.

> One way to get better reception would be to have a set of highly
> directional antennas (high gain antennas) that track a set of the
> visible satellites. Do you really want to do that?

No, of course not

> Or do you perhaps
> instead want an antenna that has a pattern that "sees" better in a cone
> with maybe a 25-40 degree elevation above the horizon, because the
> satellites directly overhead are not generally the problem? As is
> commonly the case, you should probably consider the whole system, not
> just one part of it. What, exactly, is the goal?

The goal is improving the efficiency, while not reducing (much) the directionality of a small antenna inside a plastic case that can not be modified.

Before you say this is impossible please think it twice:

Think of the small coupling loop used in a tuned loop. By itself it is a very bad antenna, but when an appropiate parasitic structure is added (the whole tuned loop) the "whole system" becomes a decent antenna. This is exactly what I'm asking about, about using my GPS antenna as a coupling to a more efficient structure of some kind.

Haven't you tried to place a walky close to a full size 2m dipole? When both antennas are paralel and very close to each other it certainly improves the signal strength.

> Cheers,
> Tom

Cheers and thaks for your answer

Quite possible, however, 13 Kc and 18 Kc fall into the VLF range. The
original poster mentioned ELF. ELF is down in the "cycles", we didn't
have "kilos" at our ELF transmitters ;)

Reg`s question was:
"What is the voltage between the bottom end and ground of a 1 metre high vertical antenna, above perfect ground, when the vertically-polarized field strength is 1 volt per metre, and the antenna height is shorter than 1/4-wavelength?"

A very clear and succinct question, I thought.

Roy Lewallen wrote:
"Relative to what?"

Reg left little to assume. I inferred that Reg had meant a ground-mounted 1-meter whip on a small base insulator. That would have left a short distance between the points of voltage determinarion.

The 1-meter whip directly over flat perfect earth must have a conjugate match to its receiver to extract all available power and get maximum voltage at the receiver input. This requires a low-loss coil to tune out the high capacitive reactannce of a too-short whip. It was specified as being less than 1/4-wavelength.

Standing wave antennas must be resonant to allow maximum current flow.

An unbalanced whip antenna must consist of two electrical parts just as a balanced antenna does. The ground or ground plane used with a whip substitutes for the missing half of a dipole. It provides a virtual image of the whip above it, to complete a dipole-like antenna. In this instance, the ground surface intervenes splitting the antenna into real and virtual parts. Radiation comes from the real part above ground. This part has only half the impedance of a totally real dipole.

We don`t need to have problems in determining the base voltage of a whip antenna. We can measure the antenna`s base impedance with a bridge, and its current with a thermoammeter with good accuracy, then we can calculate the voltage at the base of the whip.

The answer to Roy`s question is: The r-f voltage at the base of the antenna is determined with respect to ground at the base of the antenna,

Best regards, Richard Harrison, KB5WZI

Someone mentioned peak values in a posting about computer results. Since Reg mentioned a discrepncy of 2 to 1, I was alerted to a possibility of an error source. A-C and R-F instruments are often calibrated in effective (rms) values. It is also customary to use rms values in calculations. RMS is 0,707 X the peak value. Conversely, the peak value is 1.414 X the rms value.

If you multiply the peak voltge times the peak current, their product is 2X the effective (average) power..

Could Reg`s discrepancy stem from the diference beween peak and effective values?

Best regards, Richard Harrison, KB5WZI

4755. Identify Old HF Vertical

I have an old HF Vertical that is about 20 feet tall when assembled.
The loading coil (?) seems to be open (VOM). I would like to dismantle
the assembly in hopes of salvaging as much as possible to do some
experiments with it.

It could also be a CB antenna, I don't recall where I got it...

The cover over the coil seems to be plastic, but much harder than PVC.
It also seems to be tight. The bottom of the assembly where the
connector is appears to be metal. The top of the coil assembly seems
to be sealed tightly. Unless some one has a more appealing idea I am
going to chuck it up in the lathe and start peeling the coil cover to
see what is inside.

The antenna top has a couple of wires bent in an egg-beater kind of
configuration.

Doesn't appear to be any way to mount it on a mast/tower. Nor any signs of being mounted. I guess I would see if the nut on the UHF connector can be removed and the galvanized steel washer removed. That would let you peer into the thing and see what is there. May not even be a coil in there.

I am surprised you waited tis long to dismantle it!

No problem! The Navy kept fairly quiet about their ELF communications. They shut down the ELF transmitters a little over a year ago. Wonder what they're using as a replacement? They were doing experiments with a satellite based green laser I had heard (while I was still working at Project ELF)...The ELF signal used MSK modulation (Minimum Shift Keying), which is similar to RTTY, only the shift between Mark and Space was 4 or 8 Hz, depending on rate of transmission. Took 5 minutes to send 3 alpha characters...most hams wouldn't have the patience to copy at that speed ;)

Yes, this was a CB ground plane design. There should have been a bracket
that attached at bottom (metal coax connector area) and at top of loading
coil.

The application of heat with a heat gun (NOT a torch or open flame) - should
allow the plastic composite to slip off the coil.

I thought you did that with N2EY . . ?

> which the vertical flunked mainly due to an
> extremely high noise level.

I did some of that sort of A/B testing between an elevated 1/4 wave 40M GP and an 80/75/40M 130 foot end-fed inverted L a number of years ago and the GP did not fare well at all. As it happened there wasn't much of an electrical noise problem in the neighborhood then so QRN one way or the other was not a term in this specific equation.

The vertcal leg of the inverted L was spaced about 20 feet from the tower and was base-fed by a remotely controlled L/C tuner out in the back yard, a USN surplus gun director selsyn motor cranked a big rotary inductor which allowed me to QSY from 40 to 80/ 75. But the process ate a minute or two to do which was a pain in the tush during the DX contests I was into. Instantaneous band changing in that game matters.

The apex of the L was around 60 feet AGL. The 70 foot "horizontal" run sloped down from the apex to about 35 feet AGL. The L worked quite well on both bands, I could snipe JAs at will with just an SB-200 on either band from here on the east coast when band condx were decent.

I decided that I had to put up some kind of 40M antenna so that I could quickly QSY from 80/75 to 40 by simply flipping an antenna selector switch which would get me away from the increasingly annoying "twist the selsyn 30 turns" routine when band swapping.

So I built a textbook-classic 40M 1/4 wave GP which had a self-supporting 35 foot +/- radiator. The base was at 35 feet AGL, there were four downward-sloping wire radials. The whole thing perched atop the roof of the abode. SWR over the entire band was essentally unity.

Turned out to be a complete waste of time, money and effort. For whatever reason or reasons there wasn't much difference in received

signal strength levels beteen the two antennas when I was listening to long-haul DX like JAs and VK/ZLs on my end. But when I called them more times than not they did not come back to me. I spent a couple intense very early morings A/B swapping between the L tuned for 40M and the GP QSOing the DX. In 90% of the cases they "heard me much better" when I was using the L than they did when I used the GP. I took the GP down and good riddance.

I'll leave the theoretical howcums of my experince to those of you who are deep into the physics of electromagnetics. For my part another 1/4 wave HF GP just ain't gonna happen here again elevated with radials or ground mounted with gazzilion radials.

. . . half-wave verticals being a whole different ballgame . .

> I'm thinking about putting the

Also, the pressure wave INSIDE a rifle barrel travels faster than the
speed of sound. It produces velocities of the projectiles at Mach 3 to
Mach 4. Hmmm...

The air pressure profile on an aircraft wing shows supersonic, transonic
and subsonic reponses. Hmmm..

It raises a physics question. How does the velocity of sound vary in a
compressible medium as the temperature, volume and pressure change?

It has a light but sturdy bracket that I have already removed. It is
pretty rusty but I believe i will clean up well.

I have a lot of projects around here that have been waiting a lot of
years. Some of them have found new homes.

Yes, I can understand the flame front moving faster than sound, if it's not a pressure wave. I don't know the mechanism, but presume it's propagated by radiant heat. That is, a flame occurs, and its heat radiates and superheats nearby material, causing it to flame. That would be propagation by electromagnetic wave, i.e., infrared "light". The radiation would travel at the speed of light, with the apparent speed of the front being dictated by how fast the material is heated and ignited by the radiated heat. Propagation by this mechanism and at this speed would end as soon as the flame front reached the outside of the vapor cloud, beyond which the resulting pressure wave would travel at the speed of sound.

I'm not an expert at this, but I'm quite sure that the only way you can get a mechanical wave to travel faster than sound is if the behavior of the air becomes nonlinear at some compression level. That could conceivably happen as a result of an explosion, but I don't think so. If anyone has any references describing such nonlinear behavior, I'd love to learn more about it.

Hi group,

I've been researching this for some hours but can't seem to come up with some basic info. (This will be my first attempt at DIY antenna so I still have a lot to learn.)

What I'm trying to do is build an antenna for my Icom R5 handheld receiver. It uses an SMA connector. What I'm not clear on is what the internal circuitry of a receiving antenna for a handheld looks like. I'd like to start by making a 900 MHz suitable antenna as there is a lot of 900 MHz Ham activity in my area.

I'll be using my trusty mini-lathe and a 1/4-36 UNS thread tap to make the SMA connector. Q: Does anyone know what the diameter of the male pin is on the SMA connector? I have the antenna that came with my R5 but can't get into the socket to measure it.

Sure, I could buy a Pryme for $25, but why do that when I can spend $50 and build it myself? ;-)

Most MW broadcast stations use series-fed, insulated towers that usually are (by far) the highest structures in the area. These stations operate successfully in lightning storms using a combination of means. First is an arc gap connected across the tower feedpoint to a very low resistance earth ground (120 1/4-wave, buried radials). The gap is set to flash over at some margin above the peak voltage present during normal operation. They also use a "static drain choke" to earth ground, which is a high Z at the MW frequency, but doesn't let high static potentials develop on the tower. The last part of the protection system is supplied by transmitter circuitry that senses instantaneous phase changes in transmission line current, and kills r-f output for some milliseconds so as not to sustain any arc that occurs in the antenna system.

Maybe some of these techniques could be useful in amateur radio installations.

Carrier velocity is linear and must be taken into account. Relative
to a measurement point at the center of the earth, sound waves
traveling East in the surface atmosphere are moving faster than
Mach 2. Do the carriers move during an explosion?

In anticipation of a thunder storm just leave it floating. Not that it will prevent a direct lightning strike but it MIGHT prevent damage to equipment and, more important, to yourself.

But it is advisable not to attempt to disconnect it using bare fingers during the progress of a thunder storm. I am a little superstitious so I use the XYL's rubber kitchen gloves.

There's only one thing you can be absolutely certain of - lightning exactly obeys the Mathematical Laws of Probability.

See the works of Sir Ronald Arthur Fisher, the greatest statistician of all time. Beautifully explained in plain English. He dabbled mainly in Genetics, Agriculture, the Weather, and the mathematics thereof. But I'm not aware of anything specifically he had to say about the statistics of lightning strikes. You will have to work things out for yourself. In all probability nothing seriously will happen to YOU. So don't worry about it.

Just DON'T fly kites using 1/2-wavelength metal wires during thunder storms. Not even on the 10m band. Or shelter from the rain under solitary trees. It's asking for trouble but you probably won't get any.

As for me, I'm 80 years of age, and I'm still alive. I've never won the national lottery. But perhaps that can be explained by the fact that I've never entered it.

I hope the foregoing has helped to set your mind at rest.

Merry Christmas and a Happy New Year!

I am curious about the setup of measuring the input impedance of an antenna. Is there any standard setup for this? What equipments are use? Any pictures of a an example setup configuration?

I was talking to friend and I told him that you can probably use a vector analyzer to measure the input impedance at a certain frequency sweep. But I came to thinking that objects / persons around the antenna during measurement would affect its impedance due to stray capacitance. This is strictly referring to the vector analyzer fixed in a school lab setting.

Any additional info would be greatly appreciated.

Thanks!

It depends upon the required degree of accuracy. If you have
a perfectly characterized 1/2WL of feedline, you can measure
the antenna feedpoint impedance remotely within some degree
of accuracy. For what purpose is the measurement being made?

Reg, G4FGQ wrote:
"There`s no need to do a conjugate match just to measure voltage."

True. But, it`s best to measure current and calculate voltage because voltmeter leads are susceptible to induced voltages.

One benefit of the conjugate match is elimination of a reactive obstacle to current, but because source and load resistances are equal, exactly one half of the voltage induced in the antenna appears across the receiver. An infinite ipedance does not load a source at all.

Reg`s question of how much voltage is induced in 1 m of wire in a field of 1 V/m is answered clearly by Terman in publications which date back at least to 1932, the earliest copyright date I saw on "Radio Engineering". So, many competent and critical reviewers have pored over Terman`s works that it`s almost certain that any errors have been found and corrected long ago. Everybody makes mistakes, but now Terman is as close to infallible on the subject of radio as any author I know. Read page 2 of Terman`s "Electronnic and Radio Engineering" (1955 edition) for complete details. The same information appears in some other Terman authored and edited writings (almost word for word).

Best regards, Richard Harrison, KB5WZI

I'll leave the theoretical howcums of my experince to those of you who
are deep into the physics of electromagnetics. For my part another 1/4
wave HF GP just ain't gonna happen here again elevated with radials or
ground mounted with gazzilion radials. .....

Kinda weird. The one I used here worked great. And almost
identical specs. Mine was full size at 36 ft with 4 sloping radials.
The only thing I can think of to explain it , would be ground quality.
Evidentally, my ground quality must be pretty good compared to
many areas of the country. I know it's a good bit better than Cecils,
judging by the conductivity maps. If your's didn't work up to par,
I'd almost have to blame it on the radial system. I think you probably
needed a few more to equal what I had here. In fact, going by the
numbers, for a 1/4 wave at a 1/4 wave high, you really need 8 radials
to equal 120 on the ground. I judged my 4 radials as being equal to
about 60 radials for a ground mount. But...My conductivity rating in
this area is bordering on the "30" range being I'm not too far from the

coast. I know for sure Cecil would need more radials than mine for
the same performance, as his was half the height and his ground
rating is lower. .
My hunch is if you had 8 radials on the GP, it probably would have
done better.
My GP totally smoked the ground mount I had that used 32 radials.
No comparison at all. I've never tried 1/2 waves on the low bands,
except for extended inv-L's...I have run them 20m up though.
Work well there.
MK

Though what you say about measuring through a feedline is true, is there some reason you limited it to 1/2 wavelength? I regularly make measurements through an arbitrary length of transmission line--though one key is that the line not have too much loss. And of course, in making antenna measurements, it's important to realize that the feedline you use for measurement (just as the one you use to feed the antenna) may couple to the antenna and become part of the antenna. There may be some advantage in using the same line for both measurement and using the antenna as an antenna.

For the original poster: yes, an antenna system consists of what you thought was the antenna, plus its environment. People around the antenna, or big vector network analyzers around the antenna, or feedlines, or masts--any of that may affect the measured impedance. On the other hand, if you measure the antenna in the environment in which it will be used, assuming you make accurate measurements, you should be fine. You can even experiment to see just HOW MUCH effect a person near the antenna will have. Modern analyzers make this very easy and quick. Ah, for the "good old days" of hand-balanced bridges, measuring one frequency at a time! But what people actually use to make the measurement depends on the equipment they have available. Do you have specific equipment in mind?

Cheers,
Tom

HI Cecil,

> For what purpose is the measurement being made?

I think he was trying to make an FM antenna for his transmitter. We were talking about how he can design a matching network to match his antenna to his RF output. I told him that he should pick the frequency with the lowest reflection coefficient and design his matching network base on the antenna input impedance at that frequency.

Does this sound valid?

4780. Dipole antenna lobes question (wifi base in this example)

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-19 18:54:58 UTC
From: dhawo <dhawo1@earthlink.net>
Message-ID: <6mDpf.7042$3Z.1923@newsread1.news.atl.earthlink.net>
Source record: 66327

This question is not just related to wifi of course.

My understanding is if the dipoles are opposite of each other
(example 1: -----O-----) then the lobe is an equal donut
shape from the center. I would get equal focus upstairs
downstairs ends of the house if wifi base is placed in the center.
(a big vertical donut sitting in center of the house with edges
of donut touching roof, 1st floor, end to end in the house [O] <-- house)
(nulled in the front and back of the house.

What does the lobe look like if the dipoles are vertically
opposite from each other? (Example 2: |_o_|)
Is the majority of the lobe pointing to the sky and less to
the ground? Wouldnt that take away strength from the ends
of the house? Or am I totally off base? This question comes
from a recommendation that the antennas should be vertical as
in example 2. Maybe that is the idea is to lower interference
to neighbors. Thanks for all your input... Dean

If you have MicroSmith, make the load equal to 50 ohms. Set up a
series C, a parallel L, and a series C that agrees with the values
in your antenna tuner and watch the Smith Chart as the values of C
and L are changed. It's pretty interesting to see.

Dean,
Since anything around an antenna affects/distorts the radiation pattern to some extent, and since a dipole's radiation pattern is sort of directional (depending on a lot of things), the usual vertical antenna, being 'omnidirectional' would mean that the distortion probably won't mean a 'null' somewhere in the house. (Wonder if I could make that sentence a little bit longer??) That 'donut' radiation pattern is the 'ideal', not what actually happens in most cases. (There's not really a hole in the middle either.) Which would be 'beter' in your situation? Beats me. You might try it ans see, but have the vertical antenna just in case...
'Doc

You might have a look at RevLoad written by Jim Tonne, WB6BLD:

http://www.tonnesoftware.com/ (Main Site)

http://www.tonnesoftware.com/revload.html (RevLoad download)

RevLoad takes the settings of the tuner components
the system (tuner) impedance (usually 50 ohms) and
the operating frequency to calculate the load impedance
being matched. It covers all tuner configurations,
T-net, pi-net, L-net. And, best of all, it's FREE.

Still looking for a Tripp Lite PR-25 (or similar model) DC power supply
schematic to repair the club's repeater power supply. If any one has one
I'd appreciate a copy, email or otherwise.

I called Tripp Lite just now. According to Technical Support their
PRESIDENT has
recently mandated that they would NOT send any more schematics out.
However, I could trade the supply in for a new one at about 85 bucks.

Thanks and merry Christmas,
Paul.

4790. MFJ ANTENNA QUESTION

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-19 21:57:10 UTC
From: w4sef@bellsouth.net
Message-ID: <43a72aae.7737125@newsgroups.bellsouth.net>

Hello all,

I wonder if anyone has tried the MFJ collinear dipole that they have in their new catalog. It is two half waves with a quarter wave length of 450 ohm ladder line shorted at the bottom hanging down with an SO 239 connector for the 50 ohn feedline connection. I dont see why one could not build this antenna themselves. The question is, WHERE does the 50 ohm point go on the ladder line? At the bottom? Mid point? Or does it matter where it goes? I have plenty of room to put on up and wondered how well they work.

73s and thanks,

Steve W4SEF

What you have there is a Super Magnum CB antenna, vintage mid-60's. The Magnum model had 4 foot radials and no top hat. The Super Magnum has 9 foot radials with the top hat. By rewinding, or retapping the coil, you can make a great 10 meter vertical. .... or it may be simpler to change the length of the vertical section. I did the coil thing in the mid-80's and used it to work all states and 130 countries.

Terman may or may not be perfectly correct when he states the voltage INDUCED in a 1 metre high vertical antenna with a field strength of 1 volt per metre.

But Terman is ambiguous. He tells only half of the story.

He FAILS to state between WHICH which pair of points the voltage is induced.

For the UMPTEEN'th time - what I need to know is the voltage which can actually be MEASURED between the bottom end of the antenna and ground ?

I can then draw a circuit and continue with practical calculations.

PLEASE, can no-one put me out of my misery ?

Reg, G4FGQ.

4794. Z matching of antennas

Capture area is exactly the same thing as gain, but expressed in different units. There are two ways of increasing the gain or capture area of an antenna: increase its efficiency, or narrow its pattern. The former increases the gain or capture area in all directions; the latter increases it in some directions at the expense of others. A ferrite loop antenna simply has better efficiency than a standard loop of the same physical size. Hence it has better gain or capture area.

dB is a ratio, in this case of gains, or field strengths with a given power input, or capture areas. (All three ratios are the same for a given pair of antennas.) So the reference always must be specified, otherwise a statement of dB gain is meaningless. When using the gain of a free space isotropic antenna as a reference, gain is expressed in dBi, that is, dB relative to isotropic. The gain of a perfectly omnidirectional antenna over an infinite ground plane is 3 dBi, since the same power is concentrated in half the volume as it is for an isotropic free-space radiator.

I wasn't aware of that. So if typical GPS patch antennas are indeed significantly inefficient, the reception could be improved without narrowing the pattern. But I don't know if there would be any practical way to do this externally.

The civilian GPS frequencies are about 1228 and 1575 MHz. The wavelength in air of the lower frequency is about 9.6 inches. Patch antennas can be made with a side equal to about 0.25 wavelength divided by the square root of the dielectric constant of the material within the patch. So for Teflon dielectric (er ~ 2.3), a patch would have sides of 1.6 inches. If something like alumina is used (very low loss, dielectric constant ~ 10), the side would be 0.76 inches. Some patches have sides twice this long, but alumina would permit even one of those to be used in a typical GPS receiver. The two versions of patches have different patterns, and I don't know right off which would be preferable for GPS use. At any rate, I believe that patches of those dimensions are quite efficient, assuming the dielectic has low loss. Both Teflon and alumina, as well as others, meet this criterion. Maybe someone with a greater knowledge of patch antennas, and GPS antennas in particular, could provide some additional information.

Quadrifilar helices typically have four twisted half wave elements. The length for 1228 MHz would be somewhat less than 4.8 inches. Twisting would make the assembly less high that that, and fattening the elements or plating them on a dielectric substrate would further shorten them. This is consistent with the antenna of an older GPS unit I had.

It's possible to make an electrically small antenna that's quite efficient. Typical examples are the small transmitting loops made by AEA and MFJ, or the shortened, top loaded verticals described by Jerry Sevick, W2FMI, in a series of articles in the '70s. What you can't make is a short, efficient, broadband antenna. But GPS antennas don't need to be broadband. And for that matter, they don't have to be that electrically small.

This describes the approximate pattern of both quadrifilar helix and patch antennas, which is why those are the types which are commonly used.

Hi Chuck, If I read your question correctly, you want to match a 450 ohm antenna, with no reactive component, to a 50 ohm transmission line. In this case a 9:1 transformer would do the trick.
If however you are trying to match an antenna fed with a length of 450 ohm line down to the transmitter, where it will need to be transformed to 50 ohms, an "L" network or some other impedance matching network will be required. The impedance seen at the end of the 450 ohm line, in this instance, will rarely be 450 ohms resistive.

Ok Gary, I would like to match a 50 Ohm radio to a 450 Ohm antenna input. I know an "L" network would work, but what I was looking for is if an auto transformer would be as good or use a transformer with a isolated primary winding.

This has been an interesting discussion, and prompted me to do a tiny bit more research.

It seems to me that if there's any nonlinear phenomenon which allows some pressure waves to travel through air faster than the speed of sound, surely a nuclear blast would produce enough pressure to excite it. But it doesn't seem to. From http://www.globalsecurity.org/wmd/intro/nuke-blast.htm:

"During the time the blast wave is passing through the superheated atmosphere in the fireball, it travels at supersonic velocities. After it leaves the vicinity of the fireball, it slows down to the normal speed of sound in the atmosphere. As long as the blast wave is expanding radially, its intensity decreases approximately as the square of the distance. When the expanding blast wave from a nuclear air burst strikes the surface of the earth, however, it is reflected, and the reflected wave reinforces and intensifies the primary wave."

An autotransformer configuration would allow the buildup of
static electrical charges to go to ground.

Actually, I think that you already know that the gummit is talking
about furnishing STBs to poor folk and you're just being
argumentative.

From this source:

http://www.todaysengineer.org/2005/Dec/spectrum.asp

"The Senate DTV bill, passed on 3 November, calls for a 7 April 2009
analog shutoff, and would use up to $3 billion of the $10 billion
expected from the analog spectrum auction to subsidize most of the
cost for converter boxes"

After the governmental "handling charge" the $3B will eat up $6B of
the "windfall."

And after a natural disaster cable TV systems will be working about as
well as cell phones have. While the old analog TV and radio will keep
chugging along.

http://www.nab.org/Newsroom/PressRel/Releases/WSJ101504.asp

>4:3 aspect was a technical limitation that really should have died long
>before my birth, much less now. Good riddance.

What "technical limitation"? Aspect ratios are arbitrary. Most were set based on film sizes, not some CCD. Some of the finest images ever produced are on 4 x 5 or 8 x 10 film negatives, often displayed with vertical orientation, as are many of the masters' paintings; so much for 16:9 horizonatal.

Sounds like a Double Zepp with a J-Pole-like matching stub.
The antenna feedpoint impedance is very high. The 1/4WL ladder-
line stub is shorted at the bottom. At some point up from the
bottom, a 50 ohm point can be achieved, just like on a J-Pole.

Wes,

You got that right. Perhaps you are even too kind to cable service.

After Hurricane Charley hit us head on last year we saw the following outages.

Ordinary phone: 4 days (mostly underground)

Electric power: 7 days (extensive pole replacement and rewiring)

Cell phones: about 2 weeks (temporary towers brought in)

Cable service: one month (cable runs on same poles as electric service)

There was no flooding from Charley, but the winds were quite a bit stronger than Katrina and Rita.

As soon as we got a temporary generator running we were able to watch regular over-the-air analog TV.

Source record: 66356

If you have one of the Off Center Fed dipole, Inverted Vee antennas that is out there either by Alpha-delta or HamCallnet's Buckmaster 6 band antenna. It appears that all these have the insulated wire that can run around trees with no problem and are constructed with 6:1 baluns. All of them say that they work most bands great without a tuner (15 mtr not included). I'm just curious of those on the newsgroup are any of you owners of any of these antennas? If so are the reports true that they out perform most other dipoles and Vees correct?

What do you think of the antennas and would you buy it again? Also which of the OCF antennas do you own or like?

Thanks in advance

Gary

> physical size. Hence it has better gain or capture area.
==========

It's only a minor point, but when a ferrite core is placed inside a loop the efficiency remains the same. It's the same wire, the same coil dimensions, and hence the same loss in the resistance.

If anything happens to efficiency it is reduced due to a loss in the ferrite core material.

What happens is that the effective cross-sectional area of the loop increases approximately in proportion to the permeability of the core. For small permeabilities the capture area is much increased. But for larger permeabilities, say above 100, the effect diminishes and the effective core permeability settles down to the order of 20 or 30. It depends on the ratio of length to diameter of the core rather than of the coil.

To visualise, it should be remembered most of the magnetic circuit lies in the air between and near the ends of a ferrite rod. There is no point in increasing permeability of rod material beyond a certain amount in an attempt to increase capture area.

Capture area depends on the volume of the region of the e.m. field surrounding the core which is distorted by the core. See iron filings sprinkled round a bar magnet. When the reluctance of the rod itself is zero compared with that of the air path the limit of permeability has already been reached.

And high values of rod permeability are always associated with high core loss. The moral is obvious.

The sensitivity of the coil itself to e.m. waves is calculable. I'll stick out my neck and say the best a ferrite core can do is to increase the effective diameter of the coil by crudely 5 or 6 times.

Which means that the gain of your tiny pocket MF transistor radio is much better than your super-dooper transceiver which needs a 260-feet long dipole on the 160 meter band.

Just for the sake of argument!

Richard,

There is no problem with Terman's words, but I believe you are missing his intention.

His point in bringing up the magnetic flux is merely to say that one can find "exactly the same voltage" in the one meter long conductor by considered either the electric field directly or by considering the sweep of the magnetic field. It is just a statement of equivalence of the two components of the incident plane wave. This same sort of statement is found in many other textbooks.

Terman's conductor is in free space. He discusses the voltage difference between one end of the conductor and the other end of the same conductor. He does not address the question at hand, which is the voltage between a perfect ground plane and the bottom of a short conductor near that ground plane.

At least two people have explained why that voltage is not one volt for an incident field strength of one volt per meter.

With respects to antenna matching, i.e.: 50 to 450 Ohms, which is
better to use, an autotransformer or a transformer with an isolated
primary and secondary? I'm looking for the pro's and con's of each.
==========

It all depends on what you want the transformer to do besides perform
an impedance matching function.

Otherwise there's little to choose between them. The autotransformer
will have slightly less loss.

More details please.

John -

This antenna model is almost identical to one that my brother was given in the 1970s. I see you used a torch (scorch marks)..... the corrosion can be removed with naval jelly or an electrolysis process (described in boatanchors newsgroup).

You should be able to wind a proper coil and have a 1/4 or 1/2 wave vertical for 15 or 17 meters. You could use schedule 40 electrical conduit (gray PVC) for new cover of coil.

Paul -

IF it uses the standard LM723 IC regulator and pass transistors (2N3055,
2N3771, or 2N3772) you do not need a schematic per say - to repair. Check
the pass transistors with you trusty VOM/DVM .. can replace 723 !!

I've just begun (and I do mean begun!) a little refresher reading on the subject of transmission lines from a time *long* ago. I'm trying to make some sense out of why the emphasis of standing waves. The idea is familiar. Is it that somehow knowing something about the standing wave on the line that one can construct some sort of stub to smooth out the input impedance? If so, wouldn't the stub need to be tuned depending on the length of a cable? Can this be done somehow by the xmitter?

BTW, is there any analog of electrical impedance in hydraulics or other areas where waves are widely studied?

Gene Fuller wrote:
"There is no problem with Terman`s words, but I believe you are missing his intention."

I parsed Terman`s words carefully trying to avoid misinterpretation.

There is a RCA FM Coverage Calculator (special slide rule) pictured and described on the internet. Text accompanies the rule. This text says the range of the rule is for a radius of urban coverage of 1000 microvolts per meter and a radius of rural coverage of 50 microvolts per meter. They obviously anticipate a much higher urban noise level than found in rural areas.

The rule has distance scales of 4 to 100 miles, and 16 to 143 miles..

The text says: "If you hold up 1 meter of wire at exactly the right angle, this is exactly how many millionths of a volt are generated between its ends.

If you assume that 50 microvolts per meter in the country gives an acceptable quality signal at the receiver, you`ll be able to calculate how far away you can reach."

There is much more text dealing with transmitter powers, broadcast antenna types, and antenna heights. Accuracy is said to be within 10%..

I`ve never seen one of these special slide rules myself, but maybe Walter Maxwell, Richard Fry, or someone else has and can elaborate. I quoted the text because it contained in effect the simple statement that 1 microvolt is generated betweens the ends of a well placed 1 meter long wire when immersed in a 1 microvolt electromagnetic field. I certainly never expected to see that fact debated.

Best regards, Richard Harrison, KB5WZI

Gene, W4SZ wrote:
"At least two people have explained why that voltage is not one volt per meter."

Here are Terman`s exact words again:
"The strength of the wave measured in terms of microvolts per meter of stress in space is also exactly the same voltage that the magnetic flux of the wave induces in a conductor 1 m long when sweeping across this conductor with the velocity of light."

I see Gene`s statemennt as a contradiction within itself. Definition of field strength is the volts it will generate in a wire 1 meter long. There is no contradiction in Terman`s statement.

Best regards, Richard Harrison, KB5WZI

All,

I'm finally back on the air! Thanks for the antenna help, everyone. I found on the net a 30m collapsible fiberglass pole. I applied copper tape to one side as the radiator. I used layers of duct tape to reinforce every joint. I have the ground side tied to the ground rod of the trailer electrical system. No counterpoise yet. I worked a few stations tonight on 40m CW.

I am grateful for all the help, even to those who thought I wasn't listening at first.

Glad to hear it - you're on the way now.

Next, put an ATU at the bottom of the pole and give yourself some more bands. It doesn't have to be an auto-ATU - a small headband flashlight is much better value.

Then get some more wire on the ground, and you'll be surprised how 40 and even 80m perk up.

>I am grateful for all the help, even to those who thought I wasn't
>listening at first.

Your sense of what can and can't be done has been spun completely around, first by the wind and then (probably less gently) by this NG. You seem to have survived the experience rather well.

Maybe, maybe not but realistic modeling elevated HF GPs would at least
provide some hints. Maybe.

>From what I've seen, heard and read over the years there's a whole
bunch of smoke, mirrors and mythology wrapped around the effects of
radials as they relate to current-fed HF verticals. Reg Edwards
"endfeed.exe ' ditty looks like it debunks a bunch of the mythology. In
any event and with all due respect I'm not about to get into

nit-picking any of it.

The situation I described was a sort of very subjective A/B "shootout" between my two 40M antennas as transmitting antennas and the so-far strange and unexplained results I got and I seriously doubt that my results would have been noticeably different if the GP had four more radials. My voltage-fed inverted L seriously and consistently outperformed the GP on long-haul contacts as a *transmitting* antenna to the tune of at least one s-unit, sometimes more particulary into the north Pacific, at the far end. But the two antennas seemed even-up when *receiving* on my end. That's the issue Cecil brought up. The only "radials" I had under the L was a three foot long #14 wire which ran from the cold side of the tuner to a copper-plated eight foot steel ground rod driven a few feet into the ground. It BOOMED. The GP did not.

> My GP totally smoked the ground mount I had that used 32 radials.
> No comparison at all.

Yup.

> I've never tried 1/2 waves on the low bands,
> except for extended inv-L's...I have run them 20m up though.
> Work well there.

Seems like they work nicely. So far my only measurable current-era experience with true ground-mounted half-wave "dipoles" came about when I operated portable for an extended period a few years ago and strung a coax-fed 20M dipole up into a big maple tree with the bottom end of it a foot or so above the ground. Lousy location, halfway down a hill on one side of a mini-valley but "I worked every station I called". Heh. My alternative antenna then was 475 feet of wire strung thru seven trees "resonated" by some MFJ rotary inductor clunker or another which was "gounded" by 75 feet of wire from my third floor shack to the nearest patch of grass. RFI disaster site. Zero RFI with the dipole.

Anyway I'm on my way into a new location. Tiny property which will host several voltage-fed HF verticals because of their minimum-size footprints. Along with the verticals the property also hosts a rather swampy bamboo farm. Big suckers too, maybe I can raise my own quad spreaders. What do you 'spose the ground resitivity and permitivity might be? Reg and Nec-Win- Plus want to know . . .

My experience with duct tape is that it doesn't hold up well due
to weathering. I'm not sure if it was the cold, the sun, or what, but
it gradually let go and fell apart. I have no recommendations for
a substitute but someone on the group might.

I used a paint stripper gun to loosen the PVC. After I discovered that
It would not be difficult to replace the sleeve I lost interest in
trying to save it.

On the next trip to town I will get some naval jelly for clean up. The
bracket hardware needs it as well.

My current plan for this project is to experiment with short 80 and
160 meter verticals. This is pretty early in the project, I have not
constructed the radial system yet.

The focus will be on matching methods, I feel the EZNEC software
answers most of my other questions.

This is an academic pursuit!

4828. Antenna Factor

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-20 13:48:03 UTC
From: Richard Fry <rfry@adams.net>
Message-ID: <43a80ad7$1_4@newsfeed.slurp.net>
Source record: 66375

With all the earlier/ongoing posts here about the voltage across a receive antenna immersed in a known field, it may be appropriate to recall the affect that "antenna factor" has on these measured values. Here is a website with background on this:

http://www.djmelectronics.com/articles/emc-antenna-parameters-p3.html

The measured field strength using commercial VHF/UHF field intensity meters needs to be adjusted based on antenna factor to determine the real value of the incident field, using charts included with the test system documentation.

Automotive rated duct tape is of a higher quality than air-conditioning
duct tape - also more expensive. A coating of clear Krylon also helps.

Richard,

Not only are you misunderstanding Terman, you have twisted my words as well.

I said, "At least two people have explained why that voltage is not one volt for an incident field strength of one volt per meter."

You removed some of my words and completely changed the meaning.

Once more, Terman is undoubtedly correct with his statement. I agree completely. However, the configuration described by Terman is NOT the subject at hand.

73,
Gene

And just how are you going to measure that voltage without getting an opposite voltage in your voltmeter leads. Or alternatively how can you present that voltage at the input to a receiver?

You can't. So the above tells us zip about the question Reg asked. Roy answered the question correctly and you haven't even attempted it. Why is that?

I am installing a short tower. The soil is very dry, mostly volcanic ash and low conductivity. I had the backhoe operator dirll several holes 4 feet deep for grounding. It is impossible to drive a ground rod deeper than 4 feet due to bedrock. What should I use to fill the holes after the ground rods are installed?

Reg, G4FGQ wrote:
"Terman, Kraus, and Balanis and some computer programs are of no help!"

My dictionary defines "field strength" as:
"3. The strength of radio waves at a distance from the transmitting antenna, usually expressed in microvolts-per-meter. This is not the same as the strength of a radio signal at the antenna terminals of the receiver."

The definition looks OK to me. The reason the signal is not the same as the microvolts-per-meter even when the antenna is a 1-meter length of wire with just the right slant is because the induced voltage gets divided between the antenna and its load (the receiver).

Maybe Cecil`s IEEE dictionary has something to say about field strength.

Best regards, Richard Harrison, KB5WZI

You are lucky to have 4 feet. I have 8 inches or less around my house.
Zero behind the garage.

Is this going to be an antenna or just a tower for an antenna? Is the
area irrigated/watered for grass? If an antenna, you will need to
install a bunch of radials on or just under the ground surface. If you
are trying to ground the tower for lightening protection, I guess I
would mix a bunch of granular commercial fertilizer in with the soil as
I packed it around the ground rods. Then lots of water on the area.

Did you also have holes placed for guy wire anchors?

Hello,

I was curious. If a matching network was designed to make the SWR at a band of frequency less than 1.4 to 1, then what would happen if I inserted a power sensor on the line with a rated SWR of 1.05 to 1 at this frequency band?

Would that make my overall system SWR 1.4 + .05 = 1.45 to 1?

Thanks!

4841. Re: Standing Waves (and Impedance)

Newsgroup: rec.radio.amateur.antenna

From: K7ITM <k7itm@msn.com>
Message-ID: <1135102751.103538.224970@g47g2000cwa.googlegroups.com>
Source record: 66388

There are several possible reasons for being interested in standing waves (on transmission lines). Some are valid, some are not, and you'll even get plenty of, um, discussion about what's valid and what isn't.

If your goal is to get maximum power delivered to a load, then it's good to minimize standing waves on the line delivering power to that load, because a line delivering a particular amount of power to a load will have greater power lost in the line with greater standing waves. If the line is being used near its maximum power or voltage rating, standing waves are a concern because for a given power delivered to the load, the rms current at current nodes and the peak voltage at voltage nodes both increase with increased standing waves. And a high standing wave ratio on a line which is long compared with a wavelength suggests that the input impedance to the line will vary rapidly with frequency, whereas a line with low standing wave ratio will present a relatively constant impedance to the driving source, assuming the load is reasonably "flat" with frequency.

As an example of this last point, a 30 meter (~100 foot) 50 ohm line with 0.8 velocity factor and very low loss, delivering power to a 50 ohm load at 450MHz, will present a 50 ohm load to the driving source. But delivering power to a 200 ohm load, the source will "see" almost 200 ohms at frequencies where the line is an integer number of electrical half-waves long, and it will "see" just over 12.5 ohms midway between those frequencies. You get 200 ohms at 440MHz, 12.5 ohms at 442MHz--and reactive in between.

It's possible to use stubs and series line sections to effect an impedance match between a load and a line. For example, the right length and impedance series section will give you a match at one particular frequency, at least, and multiple sections can give you a "perfect" match at multiple frequencies, with (perhaps) quite acceptable match over a range of frequencies.

There are lists of analogs among electrical, mechanical, acoustic, and other media. "electrical hydraulic impedance analog" in a Google search will give you many hits.

Cheers,
Tom

No, SWR does not do a simple addition. If it is a power sensor that uses a short piece of transmission line then you have to know the frequency , the length in wavelengths, the inpedance of the line, and then do some calculations. It could be slightly beter or worse than it was to start with. Probably not enough to show on a simple swr meter.

Hi Cecil,

Thanks! I try to explain the affect of the power sensor even if it is ideally very minimal. My main concern is that at the band of design frequency the transmitter is only designed to handle 1.5 SWR max. I'm afraid that I might break it since our matching network already changes the SWR to a peak 1.40 to 1 at certain frequencies on the band.

I may have other idea. If I add the return loss of the devices, would that allow me to somehow find the SWR?

Thanks!

Hi Ron,

You leave too many issues unsaid. For one, it seems hardly likely
that you are substituting the load with the sensor, so the sensor must
be on a branch. The branch is going to have to be inserted inline,
and it is going to have its own issues.

You also say nothing of frequency. It doesn't particularly matter as
far as SWR goes, but it goes a great distance in your ability to
flatten the SWR.

You also ask "what would happen?" and that is so open-ended as to be
worthy of a 600 posting thread. Do you really want to be so vague?

You later add that your source can only tolerate a SWR of 1.5 max.
This is too too fragile by half. No doubt you are speaking of
something other that will be perturbed, but I know of no sources that
collapse to their knees under such a mismatch.

And to get back to the nut of the matter, SWRs don't add, at least not
linearly. They would be associated through a root-sum-square process.
However, with only these two numbers, the errors injected by mismatch
are trivial at ï¿½1%.

Source record: 66400

I note the subject matter of this thread is "Insertion Loss"

Insertion loss is the ratio of power delivered to a load, to the power delivered to the same load when a network is inserted between the load and the same generator.

With insertion of a passive network, such as a tuner, the insertion loss can even be a gain.

Calculation or measurement of insertion loss ALWAYS involves or implies knowledge of the generator impedance. In the present context the generator is the transmitter.

As nobody knows the internal impedance of the transmitter this thread will rapidly degenerate into nonsensical argument if it hasn't already done so.

You have been warned!

>that allow me to somehow find the SWR?

As others have told you, no, the system isn't analysed as simply as
you suggest.

Some thoughts:
- your concern that your transmitter will suddenly degrade at VSWR=1.5
is probably unfounded;
- if your power sensor is intended for inline monitoring, it should be
designed to "monitor" with insignificant impact on the load presented
to the transmitter.

You didn't tell us enough to give you a definitive answer, but it is
likely that you are unnecessarily worried about the sensitivity of the
transmitter to VSWR, and the cumulative effect of the monitoring
sensor which should be insignificantly small in the real world with
suitable / practical components.

Owen

Andy wrote:
"So the above told us zip about the question Reg asked. Roy answered the question correctly and you haven`t even attempted it."

I assumed the definition of "field strength" correctly answered Reg`s question and his descrepancy lay elswhere.

Field strength of an electromagnetic wave is expressed in microvolts per meter. It is defined as the number of microvolts which would be induced in a properly placed piece of wire one meter long.

If a field strength of one microvolt per meter does not induce one microvolt into a piece of wire one meter long, why not? I`ve been looking for an explanation and found a possible answer in Figure 2-9-1 on page 31 of Kraus` 3rd edition of "Antennas".

The possible explanation is called the "effective height" in meters of an antenna. It is a "factor", which when multiplied by the microvolts per meter of the field strength, gives the volts induced in the antenna at its terminals.

According to Kraus` figure, h is a function of current distribution in the antenna. The text says that for a dipole 0.1 lambda long, h = 0.5X the length of the antenna. Reg did not specify a frequency or wavelength for his antenna, as I recall, and he did specify a ground mounted vertical whip 1 m long for his receiving antenna.

For a dipole 0.5 lambda long, Kraus gives (h) as 0.64X the length of the antenna.

For all I know, there is a vertical antenna length in terms of wavelength for which h=1. If so, the volts between the antenna base and the ground directly under it would numerically exactly equal the microvolts per meter of the field strength. All we need to do is pick the right frequency. The applicable Formula is (1) on page 30.

I suspect that in most cases, h is determined experimentally.

I regret I`ve not had a copy of Kraus nearly as long as I`ve had a copy of Terman. I`m still using an edition I`ve had for 58 years. It shows lots of wear and tear.

Best regards, Richard Harrison, KB5WZI

That percentage must be rising now thanks to the M3/CB'ers licence as so many Hams class it. Before I would say it was very low as it doesn't involve shooting people, stealing mugging or raping. Now it takes no effort there will be plenty of them using the radios to co-ordinate robberies and gangland shootings... yeeee haaaaah good buddy.....

So what's wrong with being racist? Why let your neighbourhood turn into a shithole.....

>SWRs, like power, cannot be superposed.

Because the worse case SWR is often the concern, it can in fact be
found, not by addition but by multiplication.

In the case given, the worse case SWR = 1.4 * 1.05 = 1.47:1, an
insignificant change from the original due to the insertion of, what I
believe is an in-line sensor.

Of course, it is equally likely that the insertion of the power sensor
will -improve- the SWR.

Consider both SWRs in terms of their equivalent reflection
coefficients, rho.

$$\text{rho} = \frac{\text{swr} - 1}{\text{swr} + 1}$$

Letting swr = 1.4, rho = 0.1667

With swr = 1.05, rho = 0.0244

Worse case = 0.1667 + 0.0244 = 0.1919

Converting back to SWR = 1.473, as given above.

Best case = 0.1667 - 0.0244 = 0.1423

Converting back to SWR = 1.331

Without Gamma, which has phase info, all we know are the error limits,
the SWR is somewhere between 1.331 and 1.473.

Note: If we could make the swr of the sensor = 1.4 and put it in the
right location in the line, the net swr = 1:1. This is commonly
called a -matching network-. [g]

Someone ask for more info. Well Cecil I was thinking of matching to a Beverage antenna. From what I read they are around 450 Ohms, maybe more or less some. Most seem to use a transformer with an isolate primary, but in the ARRL antenna book, 2005, CH. 13 they show a auto transformer. I was interested in hearing from someone if one type is better then the other. I have built both types and tested them on the bench with a resistor load and they seem to work the same. I don't have the room to put up a Beverage antenna otherwise I would.

For the very last time I will repeat my question :-

"What is the voltage measured between the bottom end of a 1 metre
vertical antenna and ground when the field strength is 1 volt per
metre.

The height (length) of the antenna is much less than 1/4-wavelength.
The bottom end of the antenna is immediately above the ground. The
ground is assumed perfect. The field is vertically polarised.

Frequency, loops, reactance, radiation resistance do not enter into
the argument. No other information is needed.

Terman, Kraus and Balanis' bibles provide answers to a different
question in which I am not interested. Mere mention of these learned
gentlemen only confuses the issue.

The answer is entirely fundamental to e.m. radiation and reception.

All I need is a number of volts. What is it please?

Reg, G4FGQ.

The standard formula for the great circle distance is:

d=arccos[sin(lat1)*sin(lat2)+cos(lat1)*cos(lat2)*cos(long1-long2)]

There is no magic here; this is simply spherical geometry and
trigonometry at work.

Of course if you don't care about the great circle distance, the answer
can be anything you wish.

We did. From Cecil's QTH in Texas to mine here in suburban Philly I
could hear no
significant difference between the two antennas in A/B tests where I
didn't know
which antenna was being used (just A versus B).

But that's just one data point on one band over one path.

I think the differences were two:

First, the ground plane with four radials wasn't all that hot, and the lossy house was in the near field. The L wire was high-Z and its ground wasn't all that important. Plus the ground was high conductivity moist Aldan soil.

Second, the part of the GP with the most current, and therefore doing the most radiating, was the bottom part. I don't know how high the house roof was but it couldn't have been much more than 30-35 feet?

But the L wire on 40 meters was a full wave. High current was halfway up the sloping part, and about halfway up the vertical part.

So you probably had less ground loss and some serious polarization diversity. End result: they heard you better.

Well, you generally fill the gap there:
>that the voltage induced in a circular loop is altogether different
which is redundant to the following:
>and very much smaller from that induced in a straight wire of the same
>length.

Notably you say nothing of how much.

For the sake of novices for whom you have such paternal feelings (but
absolutely no answers) I would offer that the solution in the loop
(that same wire bent over to touch ground) and loaded with 200 Ohms
(not an open) reveals a voltage that need only be multiplied by 20 to
obtain the correct value. Trivial! And what is more, far simpler to
measure across 200 Ohms than an open at 20MHz.

Thus in response to the question:
>On Tue, 20 Dec 2005 14:40:14 GMT, Andy Cowley <andy.cowley@uwe.ac.uk>
>wrote:
>>And just how are you going to measure that voltage without getting an
>>opposite voltage in your voltmeter leads.
has been responded to fully, with a realizable design (barring this
folderol of perfect ground) and removing the objection for meter
leads. It takes no more software than the free version of EZNEC
(zipped up, but it works).

No, that's not why. The terminal voltage of an open circuited 1 meter (electrically short) dipole is 1/2 the field strength in volts/meter. The terminal voltage when terminated with a conjugately matched load can be well over a thousand volts (in the theoretical lossless case).

But it's pointless to keep repeating this. Reg keeps asking the same question, and you keep responding with the same incorrect answers. I believe I've gotten through to everyone who really wants to know the answers, so I'll let this be my last repetition.

Only as long as the emergency broadcast system is kept alive. There's no particular reason the funding for it couldn't be shut off/expanded to include cable/switch only to cable/whatever. In fact, one could argue that during a natural disaster cable TV could actually be more reliable in that its infrastructure is somewhat more protected than a huge antenna ever could be. (I seem to recall from Hurricane Katrina that some of the first phone calls getting out -- barring folks with satellite phones -- were VOIP calls over wired Internet connections.)

Not true. In the 'early days' of TV, the glass for CRTs couldn't be blown into such arbitrary aspect ratios; hence 4:3 was chosen as a reasonably compromise between producibility and "well, at least it's not square...!" :-) Presumably 16:9 is a closer match to human vision than 4:3, and for viewing a movie it would seem to make sense to try to match that since you're trying to encompass the viewer.

Hi Joel,

In the early days? I've worked on some of the oldest sets known
(albeit post WWII) that had Round tubes pointing up into a mirror for
viewing - early rear projection ;-)

I also worked on a lot of round tubes that were masked rectangular.
The mask matched the transmitted signal which was, of necessity and
technical law, rectangular. If glass blowing technology dominated the
aspect ratio, we would still be groaning about having to watch through
portholes.

The aspect ratio is called the "Academy Ratio" and it matched the
Hollywood product (hence the Academy as in Academy of Motion Picture
Arts and Sciences, the moniker for the Academy awards -AKA Oscar-
organization). When TV began to dominate the market, Hollywood
ventured into other aspect ratios (which made no more sense than the
first, and cost a gazillion times more to fabricate lenses).

==========

For starters, Have you never heard of field strength measurements?

Have you ever designed the input stage of a radio receiver?

The topic is fundamental to an understanding of e.m. radiation and
reception.

Can YOU answer the simple question? Or are you entirely dependent on
your gospel faith in 'Bibles'.

On this occasion at least, the Bibles are letting dependent people
down.

The immediate relevance to me is that I have a program which has been
reported to have a calculating error. It was reported by a person who
is not dependent on bibles. He stated that the
conventional/traditional calculating method used in my program was
incorrect. I was not entirely convinced so I posed a related question
on this newsgroup to which only one person has replied with a number.
And he was wrong first time.

Other persons who replied, after consulting their bibles, were unable
even to answer the question, either rightly or wrongly. They just
generated more confusion.

The program concerned is GRNDWAV4 which I think, but not absolutely
certain, has now been corrected. Why not download it, input a very few
standard values, and tell me whether or not it provides the correct
answer to receiver power input? You may, of course, prefer not to
commit yourself.

Is that enough elaboration for you?

in my experence the number of blacks hams is sabout half the population
numbers but YMMV

just for the halibut I have noticed the hispanic hams seem to in line
with population pretty well, asians seem a bit over the popualtion
numbers, and women are way off less in proportion than blacks, Blakc
women hams though seem relitively more numors than to balck males and
white women to white males

those are my experences as i said YMMV

Reg, G4FGQ wrote:
"All I need is a number of volts."

I`ll guess, because Reg asked, not because I know aanything. I`ve now discovered Kraus` effective antenna height which may be related to an Icelandic connection. Reg hasn`t told us everything he knows. One reason we don`t know is because the effective antenna height is related to the antenna`s length in terms of wavelength according to Kraus. One of the examples given by Kraus is a dipole of 1/10 of a wavelength. Kraus tells us the effective height of this length gives a factor of 0.5. According to Equation (1) on page 30 of the 3rd edition of "Antennas", Voltage at the terminals of the antenna = effective height X field strength.

If we guess that a short whip might have the same effective height as a short dipole, then with a 1 volt per meter field strength X 0.5 as an effective height factor, their product would be 0.5 volts. I`ll assume rms because that`s the convention for expression.

I don`t have much confidence in the number because I think you must determine the effective height experimentally. Terman says on page 991 of his 1943 "Radio Enginneers` Handbook: "If an antenna other than a loop is used, the effective height must be determined experimentally. Maybe someone has worked this out since 1943.

Best regards, Richard Harrison, KB5WZI

Hi Everyone,

I'm not sure if this is the correct newsgroup for this type of question - sorry if I've posted in the wrong newsgroup. I want to ditch my cable and go with an antenna. I'm trying to figure out what would be the best type for my location.

All the channels thatI want to pick up are less than or equal to 25 miles from my home, except for one. The one that is the greatest distance away, FOX, is 30 miles away from my home.

All of the channels that are less than or equal to 25 miles are between 12 o'clock and 1 o'clock. They consist of a mixture of VHF and UHF channels. FOX (30 miles away) is at my 2 o'clock and is a UHF channel.

Antennaweb.org says I need a large directional with pre-amp antenna in order to pick up FOX, but I can't get something that big to put on the side of my house. My wife will scream bloody murder if I did that. I have no obstructions of the sky in the directions that the antenna will have to point.

What type of antenna would be best for my circumstance? I would prefer something that is small and not very noticeable (maybe something that could pass for a DirecTV dish). Also, I would prefer to have it point in a fixed direction so that I do not have to turn it in order to view different channels. I'm planning on getting a HDTV in the near future. Do I need a special type of antenna in order to view a TV program in HD or will any antenna work?

Thanks,
CR Junk

Thanks for your reply. I have a few questions. When you say "standing waves", I take it that one can have more than one on the line?

I follow your example, but I may come back to it once I've done the calcs.

How does one know they want to improve their impedance match? Why doesn't there seem to be a need for this (probably through a balun) on a standard AM radio with a 1/2 wave line antenna or even some ferrite coil? Is there some auto-balun that works this all out?

>Do I need a special type of antenna in order to view a TV program in HD
>or will any antenna work?

I'd say that AntennaWeb is giving you pretty decent advice. It's
perhaps a bit conservative but not excessively so.

I'm operating under similar circumstances - I'm near the south of the
San Francisco peninsula about 35-40 miles away from the transmitters
in San Francisco. We get a good, clean picture using a "medium
fringe" UHF/VHF antenna (log-periodic plus corner reflector), mounted
on a 18' mast on the roof (antenna height above ground is somewhere
around 30'). We do have an amplifier for our indoor signal
distribution, but could probably get away without one if we were only
driving one or two TVs/tuners.

We don't need to use the rotator, since all but one of the stations
are north of us. The one exception is a San Jose station, which is
right "off the back" of the main antenna. We *would* need to use the
rotator, but I built a separate single-channel Yagi antenna and
pointed it at San Jose and used a combiner.

Most people around here who have roof antennas, have ones which are in roughly the same ballpark as ours... some higher, some not quite so high. The height helps a lot - an antenna down at roof level is going to "see" its horizon only about half as far away as an antenna with an extra 15' of height, and that's enough to make the difference between a clean ghost-free signal and one that's pretty noisy or ghosty.

Most TV antennas have a relatively broad forward beamwidth. Your "noon to 2 o'clock" antenna pattern is about 60 degrees, which is probably going to be workable for a standard medium-fringe log-periodic antenna design if you've got the antenna up high enough.

If you don't have enough height, then you're going to have a substantially weaker signal hitting the antenna, which would mean you'd need more antenna gain, which means a longer and more obvious antenna and a narrower beam-width, which might require a rotator.

A small, roof-mounted, non-obvious antenna which might pass itself off as a satellite dish is likely to be nearly omnidirectional, having little or no gain, and in your situation it won't "get a good look" at the transmitters (they may be over the horizon), and you won't get a good signal.

The requirements for digital TV (hi-def or standard-def) are not all that different from the requirements for NTSC analog. If you have a non-snowy, non-ghosty analog TV picture, you'll likely get a good digital-TV signal from any digital TV transmitter operating at full power. However, since most DTV transmitters today seem to be running at reduced power to avoid interference with nearby analog-TV frequencies, you can't necessarily count on getting a good digital signal lock. If your analog TV signal is noisy or ghosty, receiving digital TV properly is likely to be a problem.

Unfortunately, there's no real substitute for a good antenna, up on a mast, clear of trees and buildings and other obstructions, pointed in the correct direction. Any compromise you make from that, will probably compromise the signal to some extent.

Not only that, but also this: the antenna rebroadcasts half of the
intercepted energy.

>Maybe someone has worked this out since 1943.

Well, in fact it had been known for at least 3 or 4 decades before that. From the "Standard Handbook for Electrical Engineers," 1907-1917:

"284. Receiving Antenna. ... When an electric field of intensity E is produced on the antenna, there is an electromotive force in the antenna equal to Eh2, where h2 is the height of the receiving antenna from the earth to the centre of capacity."

As to the term "centre of capacity," this has a variable meaning according to the structure (top hats were common back then for obvious reason of the predominance of LF work) and ground conditions:

"In land stations the actual effective height is from 50 to 90% of the measured height. That the height may be made as high as possible, it is desirable to increase the capacity of the upper portion...."

n...@wt.net wrote:

Hi Mark. What's your/any definition of "par"in this context? What other
40M antenna did you A/B test against your GP on the air?

Directly, my 40m dipole at appx the same height as the base of the GP.
I also compared with the earlier ground mount with 32 radials, but
not directly, as the same radiator was used on both antennas.
When comparing the dipole and the ground mount vertical at 1500
miles, they were almost always about the same. Tested many times.
In comparison, the GP would always beat the dipole by 2 s units
at 1500 miles. Again, tested many times over a period of time.

> But...My conductivity rating in
> this area is bordering on the "30" range being I'm not too far from the
> coast.

. . maybe someday I really will download that map . . Not that I can do
anything about what it tells me about the ground condx in my particular
neighborhood .
.....

It also occurs to me that the ground off in the far field would effect
also. Being most all of this area is rated pretty well, that could be
a factor as far as low angle dx stuff... ??

> I know for sure Cecil would need more radials than mine for
> the same performance, as his was half the height and his ground
> rating is lower. .
> My hunch is if you had 8 radials on the GP, it probably would have
> done better.

Maybe, maybe not but realistic modeling elevated HF GPs would at least
provide some hints. Maybe.

Dunno. I've modeled mine, and for it to mimic real life at this qth, I
always
had to boost the ground quality in the program.

>From what I've seen, heard and read over the years there's a whole

bunch of smoke, mirrors and mythology wrapped around the effects of
radials as they relate to current-fed HF verticals. Reg Edwards
"endfeed.exe ' ditty looks like it debunks a bunch of the mythology. In
any event and with all due respect I'm not about to get into
nit-picking any of it.

Dunno. Haven't seen that yet... But I'm a pretty firm believer in what I've seen written and graphed as far as the number of radials needed to equal a certain performance of a ground mount. The lower in WL, the more you need, of course.

The situation I described was a sort of very subjective A/B "shootout" between my two 40M antennas as transmitting antennas and the so-far strange and unexplained results I got and I seriously doubt that my results would have been noticeably different if the GP had four more radials. My voltage-fed inverted L seriously and consistently outperformed the GP on long-haul contacts as a *transmitting* antenna to the tune of at least one s-unit, sometimes more particulary into the north Pacific, at the far end. But the two antennas seemed even-up when *receiving* on my end.

This is the weird part to me... I've rarely seen antennas not act reciprical as far as transmit/receive... Thats kinda unusual...

That's the issue Cecil brought up. The only
"radials" I had under the L was a three foot long #14 wire which ran from the cold side of the tuner to a copper-plated eight foot steel ground rod driven a few feet into the ground. It BOOMED. The GP did not.

Hummm....Still the only rational explanation I can think of is the GP needed more radials... Can't really think of any other reason, unless maybe the general takeoff angle was a bit higher with the GP, and again, that would tend to point to mediocre ground at , or in the far field of the antenna. Can't really think of anything else, unless maybe the radiator was a poor conductor, etc...Kinda doubt that though...

> I've never tried 1/2 waves on the low bands,
> except for extended inv-L's...I have run them 20m up though.
> Work well there.

Seems like they work nicely. So far my only measurable current-era experience with true ground-mounted half-wave "dipoles" came about when I operated portable for an extended period a few years ago and strung a coax-fed 20M dipole up into a big maple tree with the bottom end of it a foot or so above the ground. Lousy location, halfway down a hill on one side of a mini-valley but "I worked every station I called". Heh.
.
All of my 1/2 wave verticals have been base fed so far. I usually use the "gamma loop" type of feed. But...All those have been elevated, not ground mount.

Anyway I'm on my way into a new location. Tiny property which will host several voltage-fed HF verticals because of their minimum-size footprints. Along with the verticals the property also hosts a rather swampy bamboo farm. Big suckers too, maybe I can raise my own quad spreaders. What do you 'spose the ground resitivity and permitivity might be? Reg and Nec-Win- Plus want to know . . .

Dunno, but the conductivity map might give a general idea. You can d/l those things somewhere. But...Forgot where I got them.. I've got some I d/led that are in full color, and have separate charts for the various areas of the country. But there is also a little version in the

ARRL antenna handbook I think.. Texas is kinda weird as far as ground. It's real good at the coast "30", but drops to 15, or even lower as you

venture north up into central-east Texas. But there is a hot zone that runs up through Dallas, and father up into the midwest, that is rated at 30. Cecil is in the poorer "middle" zone between the two good parts.. :(It's quite possible my GP did well cuz of the decent ground quality both at the antenna, and farther away.
You should have seen my mobile on 40m at the beach a few months ago. I was parked right on the water nearly, and using my maximum length 14 ft antenna, with the loading coil at 8 ft up the whip. "antenna base at appx 64 inches from the ground, on the cab of the truck" Absolutely was kickin butt...I was keeping up with home stations running KW amps when yik yakking with various stations across the country. Was consistantly one of the louder stations to whoever on that freq.. Some were in FLA, some out west, etc.. And I was just running 90-100w from my 706. I blame it all on the salty ground and seawater...:) If that 14 ft antenna did that, just imagine what my full size GP "should" have done at that location. Dunno...I think it's all in the ground quality and radials.. Can't really explain it any other way.

The aspect ratio is called the "Academy Ratio" and it matched the
Hollywood product (hence the Academy as in Academy of Motion Picture
Arts and Sciences,.....

Lately, I've been using my puter to watch TV more than my actual
TV. Better pix, and I can putz around on the puter while I watch
all the talking heads, etc... :/
I'm using a ATI 9800 AIW card that has a phillips tuner in it.
It will shift the view for many aspect ratios. The usual 4:3,
but also 16:9, 1.85:1 and 2.35:1 in letterbox or widescreen.
Which do I usually use? The standard 4:3... :/ I generally prefer
it, and if a movie comes on in letterbox, it will show that way
even if I stay 4:3. I run my desktop at 1600x1200 res on a 21
inch monitor. The TV is much smoother than any regular TV
as you don't really see the pixels too much if you are up close.
A regular TV will look like a maze of dots if you hover up close.
This thing, you can hardly notice the pixels at all . If you sit back,
with it full screen, it's like a baby movie screen. With the 1600
desktop, if I window the TV as "large", it still only covers slightly
less than 1/4 of the screen. :/ At that setting, it's nearly like a
moving photograph. :) Kinda like psuedo HDTV...Not quite the
same, but it's semi close as far as perceived quality.
This TV/vid card is nifty cuz it also lets me record video.
So my puter is like a digi VCR. If I see something , say like
that sea plane blowing up and crashing into the water, :(, I can reach
over and record it...Yep. I did manage to record that actual crash
video..:(You can see the explosion, and the fireball definitely
following the detached wing as it fell to the water. The rest
of the plane just zipped on down to the water.. It all happened
so fast, there was no chance for them to try anything.
Kinda looked like the prop sheared off into the wing..??
I guess they will know after they look at it.

If the effective height is 50%, volts at the antenna terminals are no more than 50% numericcally of the volts per meter in the field strength when all else is optimum. This could account for Reg`s 2 to 1 discrepancy. I wonder what the speculations of Reg and his Icelandic correspondent are? Do they have a formula to predict effective height? Does Roy have such a formula? It`s a factor which won`t go away, even when ignored..

Source record: 66295

W. Watson wrote:
> Thanks for your reply. I have a few questions. When you say "standing
> waves", I take it that one can have more than one on the line?

Standing waves are created by two coherent traveling waves moving
in opposite directions in a transmission line. In a conventional
system of source, transmission line, and load, one of the traveling
waves moves from the source toward the load and is called the forward
wave. The other traveling wave moves from the load toward the source
as a reverse or reflected wave. The reflected wave is usually the
result of a load being mismatched to a transmission line. If no
mismatch exists, no standing waves are created and the system is
considered to be "flat", i.e. one forward traveling wave.

> How does one know they want to improve their impedance match?

For a transmitted signal, we establish a Z0-match to our transmitter
often at the input of an antenna tuner. When reflected energy is
eliminated on the coax between the tuner and transmitter, we know
we have a Z0-match by the SWR meter reading of 1:1. We also use our
antenna tuners to tune for maximum received signal on our S-meters.
At the Z0-match point, maximum available energy is transferred.

If you know the input impedance to a receiver, you can match your
antenna system to it to achieve maximum available energy transfer
from the antenna.

4900. antenna 'measurements' - can of worms

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-21 15:20:24 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <f4ydnVsRad8n7zTenZ2dnUVZ_sydnZ2d@comcast.com>
Source record: 66297

I have been trying to understand the characteristics and anomalies in a short loaded dipole mounted in a permanent location for some time. The antenna is a 'large' screwdriver design, capable of over a KW. Models predict a low feed resistance for this antenna, yet shack SWR readings are better then 1.1. A feed resistance of 20 Ohms or less should not result in that low of an SWR.

In pursuing this I purchased, repaired, and calibrated an HP 8405a Vector Voltmeter. This is an amazing instrument. It takes a carefully setup, however it is very sensitive. By tuning the antenna the 8405a showed two zero phase nulls very close together at 3970 KHz. One has a low SWR, the other has an SWR over 3.

The next step is to actually measure the antenna input resistance at this second higher resonance point. I then plan to wind a custom balun to match the antenna feedpoint to 50 Ohms. This should improve the performance by close to the balun ratio.

As an observation this is an example where an antenna being operated with low SWR may not optimum. I will also figure out what is happening to cause the low SWR at the first resonance point. That is still a mystery.

Be carefully, that is not exactly true. Voltage cannot be created without energy, it is a force. However once it is 'in place' it requires no energy to sustain. (Given the freshman physics caveats of frictionless pullies, massless ropes, etc.)

That said in the situation at hand of an AC voltage being induced by an EM field you are correct. The energy required to produce a voltage is a function of the impedance.

Ain't no such beast!

Anyhow, if you are looking for omni-directional, I guess you are looking at a vertical antenna. Of course it is hard to call most verticals "absolute best". If I had to have only one antenna, it would be a dipole

What are you planning on doing, how much land do you have, and are you under any restrictions? And are you going to buy or make?

Hello:

Have the following questions regarding the typical Sloper antenna to be used from
30 MHz on down to the broadcast bands. Listening only.

Would be mounted outside (high end at the house)

a. Is the most sensitive direction along the axis, or perpendicular to ?

b. If along the wire axis is most sensitive, Is there a meaningful difference in sensitivity for signals originating in the direction of the low end (low point being closest to signal origination, is probably the best way I have of delineating the direction)), or vice-versa ?

Is the answer freq. dependent ?

Thanks,
Bob

A voltage cannot be sustained without energy. The
joule of energy used to create a voltage on a capacitor
is stored in the capacitor until something changes.

Hi Richard,

For the NIST half wave field antenna:

Leff = (wl / pi) ï¿½ tan (pi ï¿½ len / 2 ï¿½ pi)

where:

len = (wl / 2) ï¿½ [1 - (.2257 / (ln(wl / d) -1))]
d = dipole rod diameter, meters

Otherwise, for very short antennas it appears it would be the area under the curve of the current distribution for the vertical element. You will undoubtedly run across the formula above, or a variant, in your copy of Kraus.

Hi Mark,

I'm a movie buff (one of my degrees) and I use a DLP projector to get a 72" 4:3 display. Last night I watched Ralph Meeker portray Mike Hammer in "Kiss Me Deadly" in glorious Black and White. The performance of Texas Instruments' digital mirror array is summed up by one of the characters, Nick, in that movie with
"Va Va Voom - POW!!!!"

2000:1 contrast ratio (my LCD monitor here only runs 800:1) and 2000 Lumens. - Oh, and cheap too compared to the field for that size (I could make it bigger, but there's only so much wall).

Got two of them. One is for presentations on the road - it cremates the dim LCD projectors others use.

Hi All,

To further illustrate the migration through the various aspect ratios, the Academy ratio was simply that of the standard 35mm film exposure. When the film is held vertically, you can see a succession of exposed images in the correct (normal to viewing) way. The image diagonal is roughly 50mm, and this is considered a "normal" lens size (by which multiples are called either telephoto 2X, 3X, or wide 0.7X, or very wide angle 0.56X). There was also the 70mm Hollywood product which was simply a double sized strip of film (first offered in the 1930 production of King Vidor's "Billy the Kid"). It was still in the standard Academy ratio.

The Academy ratio of 4:3 is usually normalized to 1.33:1 for comparison to other ratios.

When the wider (but not taller) formats were offered, things got really weird. Cinerama needed three cameras (and three projectors) to lace together the complete image of roughly 2.6:1. Super Panavision requires only one projector for this ratio.

Cinemascope replaced Cinerama with a 2.66:1 ratio, but only lasted to 1967. It accomplished this on the standard 35mm film by squeezing the image to fit the wide the of the film (this required Anamorphic lenses for exposing and projection).

With all the processes out there, I've forgotten the one that twisted the image 90 degrees to fit it on to the film strip in its wide format.

Panavision had a blighted start and wandered the field from 2.75:1 to 2.2:1. In fact when we come to the digital formats, Panavision only offered one as recently as 1999 - and, of course, the lens prices went through the stratosphere.

When you think of it, the Academy ratio still rules the digital photography marketplace. How many 2.66:1 Kodaks have you seen? Anyone find a 2.75:1 Nikon? Maybe.

For practical receiving purposes, a sloping wire, in the midst of buildings, can be considered to be omi-directional, even isotropic. Any variations in directivity, in either the vertical or horizontal planes, although they exist, are not measurable or noticeable. The random effect of the presence of a nearby building or buildings is greater than the direction in which the wire may or may not slope.

Sensitivity is frequency dependent. It falls of rapidly when the length of the antenna is less than 1/6th wavelength at the lowest frequency of interest.

Of at least as great importance is the grounding system. With ordinary garden soil you will need at least 5 or 6 shallow buried wires under the antenna, radiating from a common point in random directions. Ground wire length need be no longer than 1/12th wavelengths at the lowest frequency of interest. Lengths and numbers are very non-critical.

A sloping wire or inverted-L is the best general-purpose antenna you can get. Just erect something, not forgetting the ground.

Reg, G4FGQ.

Here is the short version:
A matched transmission line behaves like the theory books say it does. The rated power from the transmitter goes through the transmission line with the lowest possible loss to the antenna where it is radiated just like the book says.

A mismatched transmission just MIGHT work OK. If there is any possibility of generating interference, especially TVI, it will. The currents and voltages on a mismatched line are extreme... There MIGHT even be some sparks. Power loss will be at its worst for a given line. RF finds its way every where. Getting zapped once in a while eventually grows old to everyone. I remember the good old days when desk mikes were the only way to go. If you got too close, you got an RF zap on your lip. Solid state rigs don't tolerate a high SWR. They either protect themselves by reducing power or they require a lot of maintenance.

You can learn to tolerate high SWR's, but I find it worthwhile to try to keep things matched. The energy has to go somewhere, I prefer it leave here through the antenna...

Digital photography? Yuch.

Just can't beat a 4x5 view camera loaded with Fujichrome Velvia with a
Schneider lens at f45 for 10 seconds [g]. Unless, of course you use
an 8x10.

For some example see January's Arizona Highways Magazine, where fellow
Tucsonan, Jack Dykinga uses just that to capture images that will blow
your socks off.

It is true that reducing SWR for a given line does reduce the loss if
the line is long enough. (There are some scenarios where a short line
with high VSWR has less loss than matched line of the same length.)

But is matched line the real goal?

If low loss is the goal, there are often cost effective lower loss
solutions possible with lower loss line operated at high VSWR.

>A mismatched transmission just MIGHT work OK. If there is any
>possibility of generating interference, especially TVI, it will. The

Why? How is TVI "generated" by line mismatch?

Oh OO !!!

First, agreements.

1) I've used Velvia for almost 7 years. Love the saturation effects in scenic photographs. But, it's a bit too strong in portrature. I keep it for my Nikon and Mamiya systems and sccenic photos.

2) Schneider lenses are superb. Arguably, the best in the still camera market.

3) Large Format, superb film, excellent lenses make images that will blow everyone's socks off.

Note: I'd love a 4X5 view, but I'm limited to a Mamiya MF camera in 6X4.5.

Now, digital.

I have a modern design Olympus 5000 with 5 megapixel resolution. It is small and very easy to use. It is convienent. I'm dreaming about buying the Nikon D70 [I own 7 Nikon lenses and am invested in the system.]

I print 'Good' quality 4X6 and 5X7s on my computer printer. I have never tried to print a high resolution 8X10, so, I can't comment.

Future advances in CCD devices will continue to offer higher resolution. Journalism is almost 90% digital photography for it's still photos. I can go to a Professional Basketball game and shoot 300 to 600 images on one memory card; see the images immediately, delete the poor images immediately, select the better images for the editor and text author[s], and either upload or download any or all portions of the file immediately.

This saves up to one hour in processing and proof sheet review and simplifies the printing process.

Wedding photography is radically changed. During the wedding, church photos canm be distributed to the guests. Low resolution selected wedding photos can be uploaded to a web site for viewing and selection. The Bride, Groom and families can select cropping details well before final processing. The wedding photos can be delivered in high quality on a CD.

Velvia is super, but, digital is the future.

Amos, former photographer, retired.

What does this have to do with radidio?? <grin> I don't know. But, I just had to respond. <grin>

Being a contrarian, I selected Pueblo for the move, after my First Wife said she was done being cold in Gunnison. Turns out Pueblo is A Great Place to live -- unless you're trying to raise and educate children, or need to make a living. Luckily I'm not into any of that.

> Of course, Colorado Springs has tripled in size since then, and to

Source record: 66319

I am amazed that this keeps going on.

In the early days of radio, the frequencies were low, receivers were not very sensitive, and the antennas were vertical - with some understandable exaggeration. Modern circuit theory - in the sense that things can be calculated - started about 1920.

In those early days, the concept of "height" was useful. For a given physical height, one was interested in increasing the "height." Top loading was one major tool.

A simple analysis was made based on the reasonable assumption that the current distribution along a short (less than 0.1 WL), thin, rod over a good ground was linearly distributed from a max. at the base to zero at the end. Such an analysis has been made an uncounted number of times since. I found a reference that suggests that Sommerfield might have made the calculation in a paper published in March 1909. The result is always that the assumed antenna has an open circuit voltage between its bottom and ground of no more than 0.5 of the incident, vertically-polarized wave's v/m times the physical length. (An ideal 0.25 WL antenna was expected to have a "height" of 2/pi.)

No expert has ever said something to contradict the 0.5 figure. What many have described is a way to visualize E in free space using a one meter wire. That is not the subject.

Before Professor Kraus' first edition (1950), "height" had lost most of its utility. Professor Terman in his 1943 edition of -Radio Engineers' Handbook- gives it a definitional footnote on page 841. Directivity and gain had been defined and have been useful ever since.

I wouldn't say that. Voltage is kind of like having a big boulder sitting on top of a high cliff. It doesn't do anything so it doesn't expend energy. However, if it rolls off that's splat! Similarly you can have all the electrical potential you want but as long as no charges flow then where is the energy? In an EM wave it is the energy itself that flows in space using voltage and magnetism as a skeleton.

Cecil,

Still practicing physics without a license? 8-)

Electrical potential energy has units of voltage multiplied by charge.
Voltage by itself is not potential energy, literally or otherwise.

Hi Dan,

Then it appears you are not measuring the radiation resistance + loss,
but rather its transform through the tuning of the
>'large' screwdriver design

You might want to test your HP8405 against a 50Ohm load at the end of
the drive line, against known mismatched loads, and some measure of
the Q at each these nulls.

Do you choke the measurement drive line?

I didn't mean to imply that voltage and energy are the same thing.
But voltage is indeed literally potential energy (per unit charge).

Thanks. Just laid down 2 quarter wave counterpoises for 40m, and another quarter wave counterpoise for 20m. I also connected the ground system to an outside storage shed but who knows that would add. The ground system had already been connected to the electrical system ground ground, and thereby the house wiring.

Noise floor seems to be extremely high for 40 m in the afternoons and evenings, is this common?

The Eternal Squire

Thanks.
A standing wave is the sum of an incident added to the reflective wave.
Isn't it possible to send two incident waves down an xline with different
frequences, and produce two different standing waves by having some
multiplicative relationship between the two incident waves and the xline length?

Not a bad explanation from Wikipedia:

SWR has a number of implications that are directly applicable to radio use.

1. SWR is an indicator of reflected waves bouncing back and forth within
the transmission line, and as such, an increase in SWR corresponds to an
increase in power in the line beyond the actual transmitted power. This
increased power will increase RF losses, as increased voltage increases
dielectric losses, and increased current increases resistive losses.
2. Matched impedances give ideal power transfer; mismatched impedances
give high SWR and reduced power transfer.
3. Higher power in the transmission line also leaks back into the radio,
which causes it to heat up.
4. The higher voltages associated with a sufficiently high SWR could
damage the transmitter. Solid state radios which have a lower tolerance for
high voltages may automatically reduce output power to prevent damage. Tube
radios may arc. The high voltages may also cause transmission line
dielectric to break down and/or burn. Abnormally high voltages in the

antenna system increase the chance of accidental radiation burn if someone touches the antenna during transmission.

Paul -

Where are these resistors .. the typical linear supply has low ohm
equalizing resistors across the NPN pass transistors .. and only a few in
the regulation circuit off the LM723 pins .. for example a 1 K is usually
used from pin 4 to the voltage adjustment potentiometer.

Sure, it's possible but one wonders about the application.

> 2. Matched impedances give ideal power transfer; mismatched

A middle ground - Conjugately matched impedances give ideal power
transfer in the presence of high SWR. A feedline doesn't have to
be flat to be "matched". All that is required is that maximum
available power (actually energy) be transferred.

Here's a link to an Astron supply:
http://www.seits.org/features/pwrsup.htm

Assuming a typical 723 ==> pass transistors linear supply,
it shouldn't be hard to figure out the values of the cooked
resistors. The schematic at the link above serves well as a
model for many (most?) of that type of supply. Combined
with the LM723 datasheet, you can fix it.

To anybody who may be reading -

(1) There's far too much importance attached to standing waves on transmission lines. But see (4).

(2) There are colossal standing waves on antennas which are seldom taken any notice of.

(3) Anyway, of what use does anybody make of standing waves after taking the trouble to measure them. And the measurements themselves are the most inacurate in the field of radio engineering.

(4) And to cap it all, the common or garden SWR meter does NOT measure standing waves on the feedline to the antenna where they might conceivably be of interest. It's all a gigantic hoax!

Season's Greetings from Reg, G4FGQ.

The French should be given full credit for inventing the unit of
length by correctly spelling it, the "METRE".

Also, this avoids confusion with the frequently used word "METER", a
measuring instrument, when they are both mentioned in the same
sentence.

If I can manage to roll the boulder up at the top or at the bottom of
the cliff, I will find it weighs about the same. The boulder only
picks up energy as it is accelerating towards the foot of the cliff.

John,

It was really a bit of an aside, a lead into the more important point
that followed, however...

In most practical lines at HF, loss is dominated by the series
resistance.

In the regions of a current minimum on a line with high VSWR, the I^2R
losses are less than for the same net power on a flat line, and
conversely, in the region of a current maximum on a line with high
VSWR, the I^2R losses are more than for the same net power on a flat
line. Over a half wave of line, the total losses are higher than a
flat line, but a short line in the regions of a current minimum may
have losses less than the matched line loss.

Whilst that is not often to our benefit as we rarely have relatively
short lines with high Z loads, the converse is true of the more common
situation of a short line with a low Z load. For example, 3m of RG58
with a 5+j0 load (eg mobile antenna) on 3.5MHz has a matched line loss
of 0.08dB, and an actual loss of 0.66dB. Many charts and formulas
would predict the mismatched loss to be only 0.39dB, but it is worse
because the line is short and in the region of a current maximum.

>>But is matched line the real goal?

If you can't explain the mechanism by which SWR causes TVI, perhaps they correlate by some other cause. For example, an antenna may develop loose oxided connections which both change the load impedance (and hence VSWR), and create intermodulation causing TVI.

If VSWR *does* cause TVI, surely someone will be able to explain how?

Lots of people operate feedlines at high VSWR by design, and they do not necessarily cause TVI.

When you dismiss the TVI myth, you get closer to understanding how the transmission lines work and perform, and that for example, operating a feedline at high VSWR can be part of an efficient and effective multiband HF antenna. Such a solution should not be dismissed out of hand because of high VSWR alone.

Reg, I think the US was one of the relatively early signatories to the metre convention, but reserved the position to spell "metre" as "meter".

I can't recall when the UK signed the convention, my recollection is that we in VK signed it much later than both, however we metricated earlier than the UK, and the US hasn't metricated (metericated???) in the true sense of the word.

I don't miss the days of rods roods poles perches chains etc, without mentioning other dimensional units.

It might be that the same phenomenon, or related ones, have caused both the high SWR and the TVI. But high SWR doesn't cause TVI. Or feedline radiation, which is another mistaken idea.

I go along with that.

> 2. Matched impedances give ideal power transfer; mismatched
> impedances give high SWR and reduced power transfer.

That's oversimplified and a misapplication of the rule of maximum power transfer. Suppose I have a 50 ohm source connected to a 50 ohm load and adjust the source so it puts 100 watts into the load. Then I put a half wavelength of 300 ohm line between the source and the load. The transmission line will have a 6:1 SWR. There will be a 6:1 impedance mismatch at the transmission line-load junction. Yet
-- The load power will be 100 watts as before.
-- The power produced by the source will be 100 watts as before.
-- The system efficiency will be the same as it was before.
-- 100 watts will be transferred from the source to the line.
-- 100 watts will be transferred from the line to the load.

So in no way did the high SWR result in reduced power transfer.

Now change the load impedance to 300 ohms.

-- There is now a 6:1 mismatch between the source and the line.
-- The line SWR is now 1:1.
-- The load power will be reduced.

The mismatch between source and line didn't cause a high SWR on the line. In fact, changing the line impedance degraded the match at the same time it improved the SWR.

> 3. Higher power in the transmission line also leaks back into the

That's demonstrably false. For some examples and explanations, see
http://www.eznec.com/misc/food_for_thought/Food%20for%20thought%20-%20Forward%20and%20Reve

rse%20Power.txt.
(You might have to splice this URL back together if your browser splits it.)

That's true. Some transmitters can be damaged from a number of causes when the load impedance isn't approximately what the transmitter was designed for. Only one of those possible causes is increased voltage.

Of course, a high SWR can also cause the voltage at the transmitter to be lower than it otherwise would have been.

> Abnormally high
> voltages in the antenna system increase the chance of accidental
> radiation burn if someone touches the antenna during transmission.

But the antenna doesn't have an SWR, the transmission line does. If you do have an open wire transmission line, it's best not to touch the line regardless of the SWR. But if you have a high line SWR, there's just a good of a chance that the voltage at the point you touch is lower due to the high SWR than it is than the voltage is higher.

I'll bet if you search the web you can find just about any kind of possible misinformation about SWR, just as you can about any other topic.

Mismatched transmission lines also behave like the theory books say. The rated power from the transmitter goes through the transmission line to the antenna where it is radiated just like the book says.

I deleted only "with the lowest possible loss" because increased SWR does increase line loss. But if the line loss is low when matched, the increased loss due to high SWR is often negligible.

When people report "high SWR", they are usually talking about a coax-fed system, and they usually mean "a higher SWR than I expected for this antenna".

That is a big clue that the antenna is not performing correctly... but the high SWR is only a symptom. It shouldn't be mistaken for a cause.

One very common cause of RFI is common-mode RF current on the outside of the coax - in other words, the coax has become an unintended part of the antenna. The outside of the coax comes back down into the house, and can be a potent conductor of RFI. The higher than expected SWR is simply because the addition of the coax makes this a *different* antenna from the one you thought you were using.

With something like a 6m yagi, the cure is generally to change to a truly balanced feed system, and to add a feedline choke.

Obviously common-mode current is not the *only* possible connection between "high SWR" and RFI, but it's more common than many people suspect.

Just caught Roy's second post about the mistaken belief that high SWR and feedline radiation. It should be clear from the above that higher-than-expected SWR and feedline radiation are two separate *results* of unwanted common-mode currents. Once again, SWR should not be mistaken for a cause.

W R O N G !!!!!!!!!!!!!!!!!!!!

The boulder has energy simply because it is on top of the cliff.
[Potential Energy].

As it accelerates towards the bottom of the cliff the energy changes [
CHANGES] from POTENTIAL to KINETIC.

The 11th commandment: Energy can be neither created nor destroyed: just
changed in type of energy.

A*s*i*m*o*v, you need to refresh your freshman University Physicss.

4954. To Reg Edwards et al: Questions On Inverted L

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-22 12:27:19 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <tu-dnajw0KcCBjfeRVn-gg@comcast.com>
Source record: 66252

Hello, and aHappy Holidays,

Thanks for taking the time to reply to my questions re Slopers.
Am pretty new at this, and find antennas a fascinating, and quite confusing, subject.
Lots to learn, but fun doing so.

Have a JRC 545 which I really love, but obviously am not using to its full potential.
Just have a random length wire running around my attic.
Do listening only, from 30 MHz on down. Would really want something very close to omni for antenna.

Once it warms up a bit, I plan on putting up outside either a PAR SWL-EFL end fed in an Inverted-L configuration,
or possibly an Alpha Delta, or similar, Sloper.

My thinking right now is for the PAR as an Inverted-L.

Would like to ask if you have any thoughts on the PAR ?

a. e.g., in practice, is it also omni, or should I try and orient it ?
If so, is it most sensitive perpendicular to the horiz. wire axis ?

b. what would be the best ratio between the horiz. and vert. legs ?

c. I guess the end of the vertical leg should be very, very close to the Balun and ground
bar I'll be putting in. But, how does one handle 4' snow drifts getting over the Balun, etc. Is this Coax Sealer product good enough ?
Or, should I just raise the end about 4' and run some braid from the Balun to the ground bar ?

You seem very knowledgeable on all of this "black magic" so any other hints or opinions
re the PAR, or mtg and using it, would be most appreciated.

Thanks, and best regards,
Bob

For practical receiving purposes, a sloping wire, in the midst of buildings, can be considered to be omi-directional, even isotropic. Any variations in directivity, in either the vertical or horizontal planes, although they exist, are not measurable or noticeable. The random effect of the presence of a nearby building or buildings is greater than the direction in which the wire may or may not slope

Wait a minute. You said this was a "dipole", right?

If your model is operated over, but not referenced to, ground, then
ground effects are built in.

If there are sliding contacts in this antenna (I assume there are) I
wouldn't trust any rf reading until I used a good ohmmeter first.

I am glad I chose to display my ignorance, I have learned a lot.

I will modify my earlier position that High SWR causes TVI to Roy's
better explanation that they seem to have the same causes.

I have noted that other people seem to get along with High SWR's and
Non resonant antennas. Neither has worked well for me in the past.

I used to operate ATV on 440mhz with a 48 element collinear antenna.
(I did not do the initial construction) It was basically a collection
of dipoles and reflectors tied together with open wire phasing
harnesses. I could never quite figure out what the harness might be
losing. The antenna seemed to be worth about 21db with very primitive
measuring schemes. I speculated that it had a theoretical potential of
48db. I always felt that the phasing harness was the major contributor
to the losses.

With each driven element being resonant, some measure of success was
assured with each one. At 440, feed line losses get critical in a
hurry.

The transmitter final was a military surplus cavity with a 4CX250 that
had been "stuffed" to get it up to 440. As a side effect the output Z
was determined to be pretty low by trying several home brew quarter
wave coaxial matching sections. When a good match was made, a lot of
problems went away. Not only was I managing a better signal, but the
polyethylene cooling ducting was taking a longer time to melt down.

Hence, my position that SWR IS important.

Please note: I am not here to pick an argument, I recently took
W4RNL's antenna course, bought Roy's EZNEC+ program, downloaded (still
studying) Reg's many programs and have taken note that Cecil is a
motorcycle fan like my Dad was.

When I provoke an argument, I am trying to learn something.
BTW, I do have a pretty good library of reference books but you guys
explain it better in terms I can grasp!

Hi John, it was supposed to be humorous. I find it amusing that someone will say, "I hate high SWRs.", while running a resonant dipole with an SWR of 20:1 (or whatever) on the radiating elements.

Superposition and interference between the forward waves and reflected waves on the radiating elements is what brings the feedpoint impedance of a 1/2WL dipole down to 50 ohms (or whatever). If it were not for standing waves on a 1/2WL dipole, the feedpoint impedance would be in the neighborhood of 1200 ohms, similiar to an infinite dipole.

SWR can have an indirect effect on common-mode currents by causing
a malfunction of the balun. For an SWR of 1:1, the balun is probably
functioning in the impedance environment for which it was designed.
That balun may cease to choke properly when exposed to the impedances
present in an SWR >> 1:1 environment and allow more common-mode signals
to develop and radiate.

The flaw in your logic is that Google invested $100,000,000 on Current
Communications. If the trial flops economicaly, they can just keep
pouring money into it until they corner the market.

The way I figure it is they just raised $4b in a stock offering. If the
$3b left over after buying part of AOL isn't enough, they will just
sell more stock.

Every time you click on an "ads by google", you are supporting BPL.
Every time you vist a web site with "ads by google" you are supporting BPL.
If you bought Google stock, or invested in a mutual fund that did,
you are supporting BPL.

Geoff.

Energy cannot be created or destroyed. The kinetic energy gained
as it accelerates is exactly balanced by the loss in potential
energy that it had at the top of the cliff.

Consider a pendulum. When it stops at the limit of its swing,
it possesses potential energy. When it is moving at its fastest
at the bottom of its swing, it possesses kinetic energy. When
it finishes the swing to the other limit, it possesses potential
energy. Neglecting losses, potential energy at the top of the
swing is converted into an equal magnitude of kinetic energy at
the bottom of the swing and back to potential energy at the top
of the swing.

Yes, I am measuring at the end of the cable. The 8405a is configured in a balanced setup between a reference arm and an unknown arm. When the unknown arm, i.e. the antenna is terminated in 50 Ohms the line length does not matter. That was a surprise to me. The 8405a then reads the unknown at the end of the cable.

Owen Duffy wrote:
> Lots of people operate feedlines at high VSWR by design, and they do
> not necessarily cause TVI.

Here's one example where a high VSWR might cause more TVI.

XMTR--tuner--12:1 balun--5.25 WL 600 ohm feedline--600 ohm load

XMTR--tuner--12:1 balun--5.25 WL 600 ohm feedline--50 ohm load

The 600 ohm SWR is 1:1 in the first case. The balun sees
the impedance for which it was designed and functions to
choke off common mode currents with its 3000 ohms of
choking impedance.

The 600 ohm SWR is 12:1 in the second case. Neglecting
losses, the balun sees 7200 ohms, 12 times higher than
that for which it was designed. Its 3000 ohm choking impedance
may allow much more common mode current to flow and radiate
to the TV than in the first case.

Got one for you gurus and mavens.

I'm runnning an unbalanced roller T tuner through a balun to ladderline.

I want to set up a chart of mid band tune points so I can QSY reasonably quickly and with minimum fuss of knob twiddling.

I have a small antenna analyzer. Can I just put this on the rig side of the tuner, and use it to find matchpoints? Would I set it on 50 ohms, and then adjust the tuner controls until I get that?

If you have the room, a loop antenna is a very good bet. I have used dipoles and verticals for many years. A neighbor moved in a few doors down and put up a loop antenna. I went over and listened to the "quiet" It is a great antenna if you are really irritated by QRN. He has only used this type of antenna for 20 years since he tried it. I understand why. I have not yet put up one, but will. It is winter here in North Dakota and not a good time for antenna work.
Evrery other type of antenna works, but I just love the S/N ratio on a loop.

Do a web-search for "bentonite" and "ground", and you'll learn lots!

Although I've never used it (but I'm going to start!), "bentonite" is
the appropriate stuff to use. When wet, it expands inward to squeeze
the ground rod and outward to press firmly against the soil, thereby
resulting in (effectively) a very large-diameter ground well-connected
to the soil.

Clumping-type kitty-litter is supposedly bentonite (a clay material),
so it should be relatively cheap.

That will work fairly well, as long as there isn't enough
strong-signal energy hitting the antenna to confuse the antenna
analyzer and cause false readings. For example, trying to use an MFJ
analyzer to tune up an 80-meter antenna in an urban area can (I
understand) be quite an exercise in frustration, because the strong
signals from local AM broadcast stations are enough to cause the
analyzer to mis-indicate the antenna system's SWR.

I'd say, go right ahead and make these measurements... but make 'em in
pencil, and plan on verifying them using your transmitter (at low
power) and an in-line forward/reflected-power SWR meter.

> . . .

All this demonstrates is that impedance match is important to the transmitter final. The quality of impedance match is often indicated as SWR on an SWR meter when in fact the meter reading often has little or nothing to do with the SWR on any transmission line. Even when it does, the problems with the transmitter are due solely to the poor impedance match and not at all due to the SWR on connected transmission lines.

Let me give an example. Connect your transmitter through a half wavelength of 300 ohm transmission line to a 50 ohm (resistive) load. The transmitter sees 50 ohms, so an SWR meter at the transmitter will read 1:1, even though the SWR on the line is in fact 6:1. The transmitter can't tell the difference between this setup, a direct connection to the 50 ohm load, or connection to it through a half wavelength of cable with any impedance and therefore having any SWR. In all cases, the transmitter sees 50 ohms, which is all that matters. The line's SWR makes no difference at all.

If for some reason you were really interested in finding the SWR on the 300 ohm line, you'd have to insert a 300 ohm SWR meter at the transmitter-line junction. It would correctly read 6:1.

Geee-----we're on a roll! Thanks for good info on my previous query. Now, a new one:

Just put a small MFJ -949E tuner into my antenna system.

Thing works great. The only weird thing is I notice the tuning is extremely "tight" and "goosey". The slightest movement of the variable caps produces jumps in meter readings. Having said that, I can still manage with it.

Years ago, this kind of tuning effect was from hand capacity, when just about everything in the shack was RF hot.

However, this isn't what we're dealing with here. Once my controls are set, touching around the tuner anywhere doesn't alter anything. So, it's not hand capacity/coupling.

What is this effect indicative of? Just curious.

Consider the Earth-Moon system, they interact via the oceans on Earth.
The water level bulges can be considered as the pendulum in your
example. The result of the tide is that gravitational energy is being
transfered to the Moon and it is gradually accelerating away from the
Earth. So in your example the pendulum doesn't have any energy except
that which it borrows and returns to the Earth's pull of gravity. If
we were to follow your logic the Moon should fall to the Earth
instead. Assuming frictionless bearings and zero drag your pendulum
should go on forever because it has no energy of its own.

Any of several things.

This could indicate that your caps have noisy (dirty or oxidized or
burned) sliding contacts to the stator.

It could indicate that the caps have a somewhat "sticky" bearing
arrangement, which is subject to both stiction and some amount of
backlash and overshoot.

It could indicate that you are attempting to tune a highly reactive or
otherwise-difficult load, and have one or both of the caps set to a
low-mesh (and thus high-reactance) setting. If the rotor and stator
plates in those caps have the same radius throughout (I can't tell
from the picture), then when the caps are mostly un-meshed, a very
small change in the position of the rotor can make a proportionally-
large change in capacitance and change the reactance (and thus the
matching) quite a lot.

There can be a definite advantage to using air-variable caps which
have plates (on either the rotor or stator) which are tapered in
radius, from one end of the rotation to the other... it makes the
adjustments at the mostly-unmeshed, low-capacitance end rather less
critical. Take a look at a typical "broadcast variable" capacitor
from an older AM radio set, and you'll probably see this sort of
construction.

With a C-L-C T-match tuner, it's usually possible to achieve a match at several different settings of the controls. If you've achieved a match, and find that both of the caps are set up to a fairly-far-unmeshed setting, try switching the inductor down to the next-lower inductance setting, and then tweaking both caps in the direction of greater mesh (more capacitance, lower reactance). This may boost your tuner's electrical efficiency, and may also make the tuning less critical and "jumpy".

I suspect it is caused by an effective Hi-Q load on the antenna side of
the tuner. That could be a high reaactive component or a low resistive
component of the input impedance to the coax.

What kind of antenna and transmission line are you using?

I run a 140 foot long center fed doublet withh 600 ohm open wire tuned
feeders and observe the same type of indications on 60 meters. The
resistive component of the input impedance is 10 ohms with 15 ohms of
inductive reactance. It's not a problem, just sharp tuning.

A*s*i*m*o*v, Man you gotta be kidding !!!!!! The tides are responding
to the gravitational reaction of the earth-moon gravitational system;
not causing them!!!!!!!!

Yep, in the absence of centripetal acceleration the moon would crash.
But, isn't nature wonderful!! The moon has just enough centripetal
acceleration to keep it from falling into the earth. The sum of forces

on the moon keep it from flying into space or from falling to earth.

As I said in a previous post; You need to refresh your University Physics 101.

Your example suggests a simplified method of analysing the effectiveness of a balun in reducing common mode current under two different load scenarios (that happen to have a transmission line operating at different VSWR).

If the line length of your example was an even number of quarter waves, then by your own analysis method, in the second case, the balun with 50 ohm load and "3000 ohm choking impedance" would be more effective at 12:1 VSWR than the flat line?

So that goes to the meaning of "high VSWR *might* cause more TVI". Perhaps there is some other factor, and perhaps VSWR is not a root cause at all.

There is nothing in what you have said that suggests to me that VSWR is the cause of TVI (or feedline radiation in the more general case).

Roy, you are, at least, on the right track.

To measure SWR on the feedline, it is necessary to climb up the mast
or a ladder and insert an SWR meter, of the correcct impedance,
between the antenna and the feedline?

Then you have to come down safely to ground level, switch on the
transmitter, and view the meter reading through an astronomical
telescope, bearing in mind that the field of view with an astronomical
telescope is inverted with respect to normal.

In its usual position the SWR meter does not measure SWR on any line.
It merely indicates whether or not the transmitter is correctly loaded
with a resistive 50 ohms. Which is all anyone may wish to know.

After 50 years or more of ignorance, it is about time this hoax was
exposed to the world.

Then, all that is necessary to prevent the instrument from telling
lies, is to leave it where it is and change its name to TLI
(Transmitter Loading Indicator).

Reg, G4FGQ.

No. You can insert the SWR meter of the correct impedance at the input end of the feedline. Stay inside, nice and warm. Of course, if your line has a significant amount of loss, the SWR will vary along the line, so you'll have to put the meter at the point where you want to know the SWR.

> Then you have to come down safely to ground level, switch on the

That's surely a novel way of doing it, although unnecessary. On the one hand, that method might seem more plausible after finishing off a bottle of wine. On the other, that would be a bad time to be climbing the mast.

Have you had any luck in selling Agilent (HP), Narda, Anritsu, and those other ignorant companies into not specifying the input impedances of their precision RF measurement equipment, terminations, and other components in terms of SWR? Once you get them to see the light, hams will surely enlist in your jihad. Otherwise, we'll have postings from hams that go something like this:

"My TLI says my precision termination resistor has an impedance of 1.02 Reggies. But the manufacturer specifies a maximum SWR of 1.05:1. Is it ok? Reg says there are 6 dB in an S-Unit, so are there 6 SWRs to a Reggie?"

This will have the effect of reducing SWR on the line to a more
appropriate and realistic level of importance.

Who cares what is the SWR on the transmission line provided the
transmitter is loaded with its correct load resistance?

Sorry, that's not true. When the ferrite core is inserted, the loss resistance stays the same, as you say. But the radiation resistance increases, resulting in increased efficiency.

> What happens is that the effective cross-sectional area of the loop
> increases approximately in proportion to the permeability of the core.
> For small permeabilities the capture area is much increased.

This is a good illustration of why I don't like using "capture area" for antennas of small dimensions -- even Reg gets the mistaken idea that physical or effective physical area is directly related to capture area. For some antennas, like horns and ones with a parabolic reflector, it is. But for simple, small antennas, it isn't. The effective aperture (capture area) of a small loop is 3 * lambda^2 / (8 * pi) where lambda is the wavelength, for a loop of any size as long as it's electrically small enough to have essentially uniform current. Notice that the capture area doesn't increase as the loop size increases as long as the current is essentially uniform. This is, in fact, exactly the same thing that happens for a short dipole. Making a loop larger (or short dipole longer) decreases the radiation resistance which in the presence of inevitable loss, increases the efficiency. But if you could make a lossless loop or dipole, you couldn't get any more power out of it by increasing its size, again with the restriction that the current remains essentially uniform, or for a dipole that the length is very short compared to a wavelength. (The above discussion assumes that effective

aperture and capture area don't include the effect of loss. This is the assumption commonly used in texts.)

> But for

Again, adding the ferrite improves efficiency by reducing radiation resistance, not by increasing capture area.

Your reply was very fast. You didn't have time to think about it.

The only way to "measure" SWR is to place the meter at the antenna end
of the line. You know that as well as I do.

The SWR does not apply to any particular point on the line. It applies
to the WHOLE line.

I disagree with both of those statements, and both can be shown to be incorrect.

If a line is lossless, the SWR is the same all along the line. An SWR meter of the line's impedance will measure the SWR correctly when placed anywhere along the line, including at either end.

If a line has loss, the SWR varies along the line, being the greatest at the load and decreasing toward the source. (The concept of SWR at a single point is well understood and widely used and accepted, even though it deviates from the original literal definition.) In that case, the meter will correctly read the SWR at the position where it's placed. That position can be anywhere along the line including either end.

... and for most practical purposes, with knowledge of the matched
line loss, the VSWR at any other point on that line can be estimated
with reasonable accuracy from the measurement at a point on the line.

Well, I think this thread went a bit beyond where I had intended (expected?), but it looks like it's provided some useful discussions, as it did me. Here's kind of a twist on all this.

I went back to my very old physics book to see what they had to say about standing waves. Actually, I had more fun reading about waves created by a string attached to various objects at the remote end. The authors considered a case with an infinite mass at the end, and another with the end of the string fastened to a ring, which was place on a pole. Finally, they discussed what would happen if another string followed the first and the second the string was denser or less dense than the string on which the wave begin. Another time. :-)

Oh, come on....

In engineering literature an SI measurement is generally given as a number followed by the abbreviated unit in braces: 330 [cm] = 33 [m] = 3.3 [km]

Sorry for being slipshod and forgetting the braces.

The Eternal Squire

P.S. Why Santa got pulled over: 3E8 [km/s], not just a good idea, its the LAW!!!!

Dear Owen:
As I recall, very early in The Republic's life, the use of the metric system was made legal.

Rods, chains, links, feet, inches, and degrees are bound to legal descriptions of land here in The Republic in a manner that is likely to be permanent. Some land descriptions sound like this:

The east half of the NE quarter of section 24, T16N, R8W. This describes 80 acres in the corner of a specific section (one mile on each side) in the 16th township north of a reference and the eighth west of a reference. An ideal township is 36 square miles (6 by 6 miles).

Out East, some descriptions reference objects that have not been seen for a few hundred years. Precision GPS and its required antennas will, with time and care, change the some properties are described.

Hi Myron, how are you these days? If I recall, bentonite is used in
the oil patch as a slurry to seal the drill hole. It is called
drilling mud in that context. It should be pretty cheap!

Cecil:

Think about a 6 MHz wide analog TV channel. Those antennas aren't flat, and there are 2 transmitters, visual and aural. Putting an analog TV station on the air the first time, particularly low VHF, is a real interesting exercise. Or at least it was back in the stone (vacuum tube) age, the last time I did one.

Some repeaters use one antenna for two repeaters on 144 and 440 mhz.
Comercial transmitters do this all the time. Usually the transmitters are
in the same band.

I am new in ham radio and want to get set up to make the coax assemblies I will inevitably be needing in the future. I am planing on using only LMR style coax 240, 400, 600 and maybe some 900 if I get into the 1.2ghz stuff. So is it better to use the crimp, clamp or solder on connectors. In the case of the center conductor, there are some where that is solder and the outer is crimp or clamp so is crimp and or clamp ok for the outer conductor and solder better for the inner? I welcome all points of view on this. Thanks for you input.

I've just now finally gotten around to posting a response to the
NEC-list. It might help clarify things for you.

The essential point is that when you specify a plane wave source, it
acts like a plane wave of the specified amplitude coming from the
specified direction. That wave interacts with the ground plane just as
any other field would. When a ground plane is specified, the result is a
field strength -- and polarization -- which isn't generally the same as
that of the original wave. You can illustrate this by specifying a plane

wave which originates at an angle of 45 degrees above the horizon, and looking at the current induced in a short circuited vertical wire or the base voltage of an open circuited wire (the latter simulated by putting a high impedance load at the base). Begin with the wire vertical, then tilt the wire so the direction of the plane wave source is broadside to the wire, and again so the direction of the source is in line with the wire. You'll get the same result from the last two tests, and the induced current or voltage in those two is less (by about 1/sqrt(2)) than when the wire is vertical. This shows that the field is purely vertically polarized (normal to the ground plane) at the location of the wire. (I think there's actually a small horizontal component except exactly at the ground plane surface.) It does show conclusively that the orientation of the field isn't the same as it was when it left the source -- otherwise the induced current or voltage would be greatest when the wire was tilted broadside to the plane wave source and zero when tilted in the source direction.

So the interaction of the plane wave source's field with the ground plane alters both the amplitude and the polarization of the field. When the source is in the horizontal direction and the ground plane is perfect, the field strength just above the ground plane is exactly twice the amplitude of the plane wave source. So a 1 V/m plane wave source at zero elevation angle (90 degree zenith angle) produces 2 V/m just above the ground plane, which induces 1 V at the base of an open circuited electrically short 1 m vertical wire.

About 15 years ago, I put up the Alpha Delta swl sloper, hooked to a
JRC NRD 525. That was an excellent combination; strong signals. This
particular antenna is quite heavy duty, and may be a good choice for
your snowy conditions.

Have a happy...

As Doc said, solder.

Get a Weller SP-120 soldering iron. It's 120 watts. About $46. You can
typically find it by Googling.

You'll need that kind of heat to solder coax connector outer shells to
the braid. Get the ARRL Handbook, and look at their pages on soldering
coax connectors.

Clamp types have cause me problems over the years, stay away from them. Crimp type work ok in the shack but not out side for a long time. Solder it by far the best way to go. Another type that works good outside is compression clamps. The ones meant to be used with hard line. They cost more, but unless you like climbing up a 60 foot tower in a contest, they are worth the cost!

Solder - the only way to go.

Also, check out The WireMan (http://thewireman.com/index.shtml) for coax, connectors and their cat. (Wirebook III) has a real good section on soldering.

hi Chris,

Welmcome to ham radio, I am sure you will enjoy it
as much as the rest of us have !

Since you are starting out, to solder you just need
the iron, 100-120 watts with chisel tip is just fine,
don't attempt with the lower wattage units, you end
up damaging the coax dielectric and have more problems.

Crimps have their place, but, you will need to buy or
borrow the crimp frame tool along with the correct
dies for the connectors you want to crimp.
This is a lot more expensive then the solder iron.

Be sure to buy and use name brand connectors,
quality is worth the price, you buy it once.
You can get a bag of the cheap ones to practice
with and then use the good Amphenol or other brands.

http://www.amphenolrf.com/products/assemblyInstructions/274.pdf

The above pdf has installation instructions.

Reg,G4FGQ wrote:
"---when a ferrite core is placed inside a loop the efficiency remains the same. Its the same wire, the same coil dimensions, and hence the same loss in resistance."

Not if the coil is doing the same job. Remember the permeability tuned coils? You insert the core farther into the coil to increase its inductance. The powdered-iron core has a much higher permeability than air. The powdered-iron core gathers and concentrates lines of flux inside the coil. If the iron-cored coil is to resonate at the same frequency as the air-cored coil does, the iron-cored coil must have many fewer turns, and thus it has much less loss. Good design requires a ferrite with low-loss at the frequency.

For a ferrite loopstick antenna, sensitivity is proportional to the length of the ferrite rod and best placement of the coil is squarely in the middle of the ferrite rod.

Best regards, Richard Harrison, KB5WZI

Source record: 66204

Roy, you surprise me. Try a jug of Moonshine.

Placing the SWR meter at the start of the feed-line terminated by the antenna, will tell you NOTHING about the SWR on that line.

It is the antenna input impedance which determines the SWR on the line, and the meter doesn't have the foggiest idea what THAT is.

The unknown antenna impedance is at the other end of a line of unknown length, unknown impedance and unknown loss. Unknown, that is, to the meter.

YOU might have that knowledge. But then you can CALCULATE what the SWR is on the line. Meter readings having been discarded as useless.

I repeat - the meter tells you only whether or not the transmitter is loaded with a resistive 50 ohms. No more and no less. If it is not 50 ohms the ambiguous meter will not even tell you the actual value of Z.

Intoxicated or not, if you insist on a meter reading, there is no alternative to climbing the antenna mast.

Reg, G4FGQ.

PS. The use of SWR by American plug and socket manufacturers to describe unrelated characteristics of their products is a small indication of the abysmal depths to which engineering has descended. Technical specifications are reduced to Camm's Comics. But they look good to the uninitiated.

Reg.

Bob wrote:
"What would be the best ratio between horiz. and vert. legs?"

Short answer: Zero. All the wire should be vertical for best results.

Try to borrow a copy of ON4UN`s "Low-Band DXing" published by ARRL. Look at page 9-48 for the radiation resistance (good) for an inverted-L with various ratios of horizontal and vertical portions. Mistly, this is a vertical antenna with the forizontal section providing top-loading.

Best regards, Richard Harrison, KB5WZI

If you follow the amphenol instructions, they omit one thing. Take a little
extra fine grit paper and clean the areas where you will be applying the
solder. It can never be too clean, and there is often a little corrosive
film which you cannot always see with the eye that develops over time.

I am absorbing this, but slowly.

I have understood that a "matched line" would indicate the same SWR at
every point you might measure it with a directional coupler. The Swr
we are discussing is that which we can measure with a directional
coupler, is it not?

The SWR on a mis-matched line will vary with the position you choose
to measure it. This can be indicated by varying the transmission line
length to get an acceptable match for the system. This will satisfy
the need to match a transmitter for a given frequency. A directional
coupler placed at different places on the line will still indicate a
non uniform SWR. Any feed line losses due to insulation or radiation
are effectively hidden from the transmitter end.

This is why I have gone to the antenna/feed line to measure the power
level and the SWR. If your feed line has become an effective dummy

load or a better radiator than your antenna it would nice to know.

I don't have an answer as to how to measure the instruments insertion effects.

Please tell me where I am in error!

If it's a 2 story house, I would try something in the attic. I have a Radio Shack $24.99 UHF Corner Reflector Yagi on the vent pipe up on the roof with a rotator and ChannelMaster amplifier. My local stations are 26 - 35 miles away. Most days I also get HDTV from Philadelphia stations 64 miles away. A lot of this is going to depend on how much power the stations are transmitting. The stations I am picking up are 100KW to 700KW. VHF stations will operate with a lot less. The orientation of the house is such that you can not see the TV antenna from the front of the house.

Crimp connectors work just fine when done properly, but I would not use them on anything above 2M. You will find the compression type fittings for larger coax and heliax superior to anything else for microwave work.

But most will probably suggest generally a good soldered connector the best for most apps.

If you have the money, the best iron for soldering coax connectors would be one such as made by American Beauty..... but very pricey. A hefty Weller gun will suffice if funds are limited.

Another trick: it's usually possible to solder the outer shells into
place with a lower-wattage gun, if you first pre-heat the whole
assembly with a hot air gun (hair dryer might work). This can be
gentler on the coax (and its meltable internal insulation) than just
hitting the shell with a soldering iron and waiting for the shell to
soak up enough heat to allow the solder to melt.

Actually I plan on going out of my way to avoid UHF connectors. I plan
on doing a fair amount at 400+ mhz and the UHF connectors don't do well
up there. So about the only place I will be using UHF is at the radio
if I can't find a radio with N connectors. My watt meter has N
connectors and so do my antennas. I'm not sure why anyone would want to
use UHF on anything outside. The only way to protect a UHF from the
weather is with some coax wrap but the N has a seal built in, of course
some kind of wrap as additional protection isn't a bad idea either if it
is done right. In some cases I may even replace the UHF connector in
the radio with an N but only if it is an old radio no longer under warranty.

Then why is it that Times Microwave only shows how to put on crimp and
clamp connectors on their cables on their web site. On their larger
cables (LMR 900 and up) they only have clamp connectors.

>You will find the compression type fittings
>for larger coax and heliax superior to anything else for microwave work.

I found an 150 watt one for $115, that doesn't seem too bad to me if it
is that much better than others.

http://www.hmcelectronics.com/cgi-bin/scripts/product/0400-0027

One thing I forgot to mention in my first post, where you have to use a
UHF, it seems that for LMR 400, the only option is solder, I could be
looking in the wrong places, but I haven't seen any crimp or clamp on
UHF connectors for LMR 400 only solder. About the only time I plan on
using anything smaller than LMR 400 is for a jumper to hook my hand held
to the big antenna, for that I am going to get some LMR 240 ultra flex.

If you are going to crimp and use it outside you certainly need to use some good adhesive lined shrink tube to seal it up. I'm curious why no one seems to like crimp. Other than the cost of the tools to do it right it seems like a much easier way to go. Crimping works great for other types of connections. Also I did a lot of browsing on Times Microwave's web site and about all they talk about are crimp and clamp on connectors, for the big cables it is clamp only, I think part of the reason for that is you would probably need a hydraulic crimping tool for those big cables :)

I like those, the only connectors I have put on so far is a solder/clamp N and a solder UHF, the N was a solder on pin, which was pretty easy and then the clamp on outer shell. The only hard part was getting the cable striped cleanly but a good coax stripper should fix that. That is the next thing I plan on buying, I just need to find a good one.

A matched line is one which is terminated with its characteristic impedance. The SWR on a matched line is 1:1 at all points along the line.

> The Swr
> we are discussing is that which we can measure with a directional
> coupler, is it not?

Yes and no. To measure the SWR requires an SWR meter or directional coupler which is designed for the particular characteristic impedance of the line. If a directional coupler is the proper impedance, it can be used to calculate the SWR from the forward and reverse powers. If it isn't, it can't.

> The SWR on a mis-matched line will vary with the position you choose
> to measure it.

No, it won't, unless it has loss. If it has loss, the SWR will be greatest at the load and will monotonically decrease toward the source.

> This can be indicated by varying the transmission line
> length to get an acceptable match for the system. This will satisfy
> the need to match a transmitter for a given frequency. A directional

It appears that you're assuming that what you measure with an SWR meter or calculate from directional coupler readings is the SWR. Unless the coupler or meter is designed for the Z0 of the line, it isn't. If the coupler or meter isn't of the proper impedance for the line, you'll get different readings as you move along the line. Those readings aren't, however, the line's SWR.

I forgot to bring up resistive soldering, does any one use one of
those? I guess if I get a big iron that will work good. I used a 140
watt gun for the UHF connector I did first, I hear the big irons work
better because of the larger thermal mass, I may try the heat gun trick
too. I have a small heat gun that will get up to 200 and something F or so.

This is pretty strange.

Suppose Reg has a 50 ohm line of some length connected to an antenna whose impedance is 100 + j0 ohms. After putting away his evening's bottle of wine, he climbs the tower and inserts a 50 ohm SWR meter at the antenna. He climbs back down, gets out his vintage brass telescope and keys the transmitter. Then, steadying himself, he peers through the telescope and sees that the SWR meter reads 2:1. (Being a clever person, he mounted the meter upside down so it would be right side up in the telescope, obviating the need for the added challenge of mental inversion.)

I have an identical antenna, feedline, and SWR meter. I sit in my warm shack sipping my moonshine, connect the SWR meter to the input end of the line, hit the key, and note that the meter reads 2:1. Or perhaps slightly less if the line is noticeably lossy.

Reg says:

> Placing the SWR meter at the start of the feed-line terminated by the
> antenna, will tell you NOTHING about the SWR on that line.

I guess the 2:1 reading from the meter at the input end of the line is telling Reg nothing, while the 2:1 reading at the antenna is. Strange. The fact is that it's the SWR on the line, and it can be measured at any point along the line. I like my method better, but each to his own.

Roy Lewallen, W7EL

One thing I should have said was that I use ONLY "N" connectors from 144 to 1296. I read, maybe in this group, that UHF connectors are ok to 500MHz. Like I said, I don't use them above 144MHz. and I know some hams that don't use UHF connectors on 6 meter. Above 2304 I use SMA's and WG on 24GHz. I'm getting off track, solder is the best way to go for UHF, or use whatever "N" connector Time recommends for their cables.

~~~~~~

That's my preference too. Weller makes a 250 watt gun that works great
for PL-259s. Heats up in a few seconds, unlike an iron, and cools down
quickly. Be sure you get the 250 watt version, not the 125 watt.

In all honesty, I don't have any real experience on most Times'
Cables..... mostly with Belden and Alpha products, so can't be sure what
connectors Times recommends for their larger RF cables.

>> If you have the money, the best iron for soldering coax connectors
>>would be one such as made by American Beauty..... but very pricey.

> I found an 150 watt one for $115, that doesn't seem too bad to me if
> it is that much better than others.

I think most experienced technicians would agree that the large mass
of the heating element on the American Beauty allows for a better and
quicker solder job, with much less risk of damaging the cable. If you
don't mind spending that money, I'd recommend the one you linked to. I
have one similar to it, and no regrets.

The program zl_zin calculates a Zload from a known Zin. It would seem that given a symmetrical feedline that Zin and Zload should be mirrors. Why is that not so?

Is there a program that will calculate Zin from a known Zload?

Thanks - Dan kb0qil

Roy,

Plot this on a smith chart program. You are correct, your meter reads close to 2:1, however you know nothing about the phase or resonance of the antenna. It does not tell you if you have a tuned antenna and a poor R match or if your antenna is way out of tune. (Of course neither does the telescope)

In this day and age, there is only one meter on or associated with a transmitter.

It is the misnamed SWR meter.

Consequently and unavoidably, with nothing else left to talk about, the importance attached to SWR becomes exaggerated.

It is perfectly natural, for CB-ers and professional engineers alike, to imagine the indicated SWR applies to the one and only transmission line in the system. That is along the line from the transmitter/tuner to the antenna.

But the meter does not indicate SWR on any line. It merely indicates whether or not the load on the transmitter is 50 ohms. Which is nice to know. But, nevertheless, you have been fooled!

After half a century of being unwittingly misled, it is admittedly difficult to have to suddenly switch one's ideas about what is thought to be an important subject.

Carry on arguing!

Reg.

I'm not sure what you mean by "mirrors". But the relationship between Zin and Zload is dictated by the way transmission lines transform impedances. A better question is, why should it be anything else?

A series inductor is symmetrical, is it not? Suppose you have a series inductor with impedance +j10 ohms in a box. Connect it to a load of 50 + j0 ohms. Looking into the input of the series inductor, you see 50 + j10 ohms. Now put a load of 50 + j10 ohms at the output instead of 50 + j0. Are you saying you expect to see 50 + j0 at the input? Why?

> Is there a program that will calculate Zin from a known Zload?

Hopefully someone else will be able to answer that.

What you say is true, but I don't understand what it has to do with the discussion at hand. No one has mentioned phase, resonance, tuning, or R match. An SWR meter isn't a suitable tool for measuring any of these, except that it'll usually indicate the resonant frequency fairly closely for most typical antennas.

Roy,

Well the intuition was correct, however the problem is one level more complex.
The Smith chart shows the following approximate 'mirror' relationships for j=0:

Load Input Measurement
20 125
25 100
35 71
10 250
50 50

It is a "log" mirror centered on 50 Ohms. The mirror relationship holds for j /=
0, however the calculation is more complex. - Dan

Let's not be fooled by these contrived misstatements.

An SWR meter tells us the SWR on a transmission line to which it's connected, providing that the line and meter impedances are the same. This can easily be verified with a couple of simple experiments. So it does indeed indicate the SWR on a line. It will, of course, still give a reading under other conditions, such as when the line and meter Z0 are different or when there's no line at all, in which cases it means only what Reg says(*). But I'm afraid that the effort to leave a legacy of a new TLA (three letter acronym) for SWR meters is causing Reg to adopt an increasingly distorted view of what SWR meters can and can't indicate.

(*) Any kind of test equipment can be misused or the results misinterpreted. For example, anyone using a 1000 ohm/volt voltmeter to read voltage in a high-impedance circuit will not see the voltage which is there when the meter is disconnected. Likewise, measuring high frequency waveforms with a 10 pF scope probe, even at moderate impedances. The list is endless. But this doesn't justify renaming each of those pieces of test equipment to accommodate the most naive user.

=========================================

Yes, from the same place you obtained program ZL_ZIN.

For coax lines use program COAXPAIR.
For balanced twin lines use programs RJELINE3 or 4.

These programs are to professional standards, 1% accuracy or better,
covering the frequency range from audio to UHF.

Roy, I also wasn't quite sure of the concept of *symmetry* and
mirror as used by Dan.

I made the assumption (perhaps incorrectly) that the transformation is
symmetrical for an integral number of half waves of lossless
transmission line. Impedances might be seen to "mirror" (if mirror
means an exact copy) for an integral number of half waves of lossless
line.

Having made that assumption, loss introduces errors to the
"mirroring", and line lengths other than an integral number of quarter
waves aren't symmetrical in that sense.

Having read Dan's further comments, it seems he thought any length of
real line was symmetric as an impedance transformer. It might be that
you can swap A and B ends in a circuit and obtain the same behaviour,
but you can't swap Zload and Zin in the general case.

Dan, the terms you have used don't have common usage in this context,
and confuse the issue.

You only need low power iron to attach the
center conductor to the pin, the N connectors
are clamp types. No tools needed.

Yes, the 3/8" chisel tip is great.

100w or higher 700 deg. autotemp weller.
many used on the forsale forums and ebay.

Big difference between a heat sink and heat source !

From: mcalhoun@ksu.edu
Message-ID: <doibpd$fkt@unix1.cc.ksu.edu>
Source record: 66138

I've long used an end-to-end pair of same-band hamsticks on a metal
bracket at the top of a push-up pole for a quick-and-dirty expedient
dipole. My support pole is usually wood, but when I put the dipole
on top of a metal pipe I realized there are two ways to do it:

The hamstick that is connected to the coax center wire
is always insulated from the pole, and the hamstick
that is connected to the coax shield could EITHER be
INSULATED or "GROUNDED" to the pole.

QUESTIONS: Which should it be? Should/Would it make any difference?

Well, yes, you can find specific relationships for various special cases of load impedance and line length, particularly if you assume zero loss. But only the appropriate equations, derived from basic principles, will give you the correct relationship in the general case. Be wary of oversimplification.

I suspect that connecting the shield would be better. Connecting the
shield and using a 1:1 balun at the top would be best.

If you have the ARRL Antenna Book (I have the 19th edition) page 24-21
talks about PL-259 assembly, and explains how to prepare the coax and
solder it to the connector. This is in the chapter labled
"Transmission Lines" if you have another edition of the book.

You should not dismiss crimp connectors as inferior to soldered connections. Crimp connectors, properly executed with correct fitting dies, produce a very good result, they are good electrically, and they often have superior strength compared to "field serviceable" connectors (the solder / braid clamp) type.

For my own use, I:
- avoid PL-259 type connectors (that is not to mean UHF);
- prefer N type for thicker cables and all outdoors (whether or not in the weather);
- on Heliax, prefer the connectors that are sealed by injection of silicone into the backshell, ambivalent about whether the centre pin is soldered or spring contact (which are usually cheaper and quicker);
- prefer BNC on thin patch cables and fly leads;
- prefer crimped connectors to "field serviceable" connectors in indoors applications;
- prefer sealed connectors for all outdoors applications, and question whether most sealed crimp connectors are actually effective through life;
- keep a pair of multigrips handy for times when UHF connectors must be used.

If you are choosing to use LMR cables, you might want to look at LMR195 (I think) which is dimensionally similar to RG58 and can use low cost RG58 crimp connectors.

If you use BNC (or TNC for that matter), look at whether the connectors you buy locate / retain the centre pin independently of the wire connection.

5047. Re: Standing Waves (and Impedance)

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-24 04:33:16 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <doij2c$5oi$1@nwrdmz01.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 66144

The so-called SWR meter is just a resistance (not impedance) bridge.

The bridge is at balance and indicates SWR = 1:1 when a resistance of precisely 50 ohms is connected to its output terminals. It is arranged within the meter that this 50-ohm resistance, or whatever is connected to the output terminals, is the transmitter load.

With the meter in its normal location, the load is the input impedance of the transmission line to the antenna. So when the input impedance of the line, as determined by Zo of the line and the antenna input impedance, is 50 ohms then the meter indicates SWR = 1:1 regardless of Zo, line length and antenna impedance.

As Roy says, in the special case of line Zo being precisely 50 ohms it so happens that the meter will correctly indicate SWR along the line. For any other value of line Zo the meter will indicate varying degrees of nonsense.

At HF, line Zo is frequently anywhere between 50 and 600 ohms and a tuner is used to transform line input impedance, either up or down, to the 50 ohms required by the transmitter. But Zo is not affected and the SWR meter indications remain in error.

Whatever Zo and antenna impedance may be, the meter always indicates whether or not the transmitter is correctly loaded with a resistive 50 ohms.

Note that the circuit operates independently of transmitter internal impedance whatever that may be.

~~~~~~

What would be the point of "grounding" it to the pole? Do you want
some of your RF to flow into the pole and thereby have the pole
radiate? I wouldn't.

The HamSticks are your antenna. Don't add something else unless you
have a specific reason.

The 1:1 balun mentioned by someone else is a good idea. It will keep
all the RF in the antenna and prevent any from flowing on the outside
of the coax. If you choose to not use it, it's not a major deal but
that would distort the antenna pattern a small amount.

short answer: there is no 'ideal' length.

long answer: an 'ideal length' is a metaphysical concept that has no place in engineering. antennas of different lengths perform in different ways as governed by the laws of physics, obviously the designers of those antennas made some tradeoff in length vs signal strength vs distribution of energy in azimuth and elevation vs installation location and physical limitations including probably visibility, strength, produceability, and mounting method to come up with a cost effective solution to the problem of letting a user make phone calls from car. the concept of 'ideal length' assumes that there is one length that gives the best of all those possible tradeoffs which is highly unlikely to exist.

As Dave said, there is no ideal length for an antenna.

The 1/4 wave antenna will have a radiation patern that sends much of the signal at high angles from it. Not usually good for cell phones where they are usually on short towers (if you call a couple of hundred feet short). The longer (in wavelengths) antennas tend to put the signal more to the horizon and not overhead. By modifying the radiation patern to put it more where it is needed instead of where it is not needed you get gain in that direction and hopefully longer range.

What an absolute load of blx.

The reason that car cellular antennae are longer than a 1/4 wavelength is that almost all of them are centre loaded dual antennas or are 5/8 or 7/8 co-linears. The very short ones are often a little longer as they are coupled through glass and have to be matched.

The wavelength of a signal and it's aerial have nothing to do with the propagation pattern. A simple VHF or UHF folded dipole for the same mounting and wavelength related structure spacing radiates the same shape of pattern irrespective of frequency - roughly apple-shaped in cross-section.

What you are getting mixed up with is the panel aerials used on most base station sites. These are almost all multiple stacked element arrays which are designed to project the signal more outwards and not down/close in, and they amost always are spaced within the package to make them directional after a fashion. Many of them have 5 deg or 10

deg of electrical downtilt to give the close-in coverage, hence why you sometimes see the 'rabbit ears' tilted backwards where range is important for that particular location.

I'm a cheapskate who uses a soldering gun about as often as I make new
coax lines. (It happens, but I don't spend much time at it.) If you
have a Harbor Freight tool store near you, they have a 180 watt gun you
can usually catch on sale for 6.99. Not as good as a Weller, I'm sure
but so far the solder hasn't noticed.

==========
"Transmission performance" is just a descriptive term relating to how well a line works compared with what is expected from it. It is not measurable. It is a way of referring to the very many different characteristics / properties / attributes of anything which performs. It can be good, poor, better, worse, etc., etc.

The "reflection coefficient" is a dimension-less ratio, the mathematical relationship between line Zo and the line terminating impedance Zt.

RC = (Zt - Zo) / (Zt + Zo).

In general, both Zt and Zo are complex quantities and therefore RC possesses both magnitude and a phase angle.

The magnitude can be anywhere between 0 and 1+Sqrt(2) although only in very exceptional circumstances will it exceed 1.0 It is never expressed as a percentage.

The phase angle can lie in any of the 4 quadrants of a circle. i.e., it can have an angle anywhere between 0 and 360 degrees. When performing calculations it is more comvenient to refer to the angle as lying between -180 and +180 degrees.

It can be referred to any point along a line. The angle, as in a vector, rotates as the reference point moves away from the termination towards the generator.

As you are probably aware, RC is closely related to SWR. SWR can be calculated from RC. But RC cannot be calculated from SWR. This is because RC conveys twice the amount of information as SWR. When calculating SWR from RC half the information is lost. The angle of SWR disappears.

SWR is the end of the line! Whether SWR is measured or calculated you can't go much further.

But SWR / RC is a fascinating subject.

Reg, G4FGQ.

5061. Effective Height of Vertical Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-24 16:58:53 UTC
From: Richard Fry <rfry@adams.net>
Message-ID: <43ad7d96_3@newsfeed.slurp.net>
Source record: 66157

Recently I bought a used copy of "Reference Data for Radio Engineers" published by Howard Sams in 1975. On page 27-6 the following applies to this topic:

QUOTE

The effective height of a grounded vertical antenna is equivalent to the height of a vertical wire producing the same field along the horizontal as the actual antenna, provided the vertical wire carries a current that is constant along its entire length and of the same value as at the base of the actual antenna. Effective height depends upon the geometry of the antenna and varies slowly with wavelength. For types of antennas normally used at low and medium frequencies, it is roughly 1/2 to 2/3 the actual height of the antenna.

For certain antenna configurations, effective height can be calculated by the following equations.

Straight Vertical Antenna: h =< 1/4 lambda

Effective Height = [lambda/pi*sin(2*pi*h/lambda)]*sin^2(pi*h/lambda)
where h = actual height

<clip>

END QUOTE

This may be useful toward the earlier thread started here by Reg ("Back to fundamentals"), that went off in several directions.

Message-ID: <6gfrf.57587$6e.57437@tornado.tampabay.rr.com>
Source record: 66160

If you live on a typical suburban lot and were contemplating purchasing a Yaesu FT-857D or perhaps the new Icom R-7000, what would you buy for an antenna(s)? Is the QRN bad enough that you would stay way from a vertically polarized antenna for HF? Should I take an interest in 160 meters or is it a relatively specialized band that is not worth the antenna considerations initially? Been away from Ham radio for over 20 years but know enough to think out my antenna strategy before buying the rig. Thanks for any comments.

Cordially,
west

5063. EZNECv4 Loop Modeling

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-24 17:15:57 UTC
From: Jim Miller <jim@jtmiller.com>
Message-ID: <1135444557.417573.286740@z14g2000cwz.googlegroups.com>
Source record: 66158

I finally took the time to do some modeling using EZNEC v4 of a loop I'm going to build. I used the loop facility in EZNECv4 to construct a circular loop approximated by 32 linear pieces each of a single segment. I placed a lossless 23.2pf capacitor (series RLC with R,L as shorts) in the center of the topmost segment. The "wire size" for this portion was 0.875" corresponding to the 3/4" soft copper I'm using. The loop size was 5.25ft in diameter just short of a 1/4 wave at 20M.

I then constructed a 1/5 diameter loop of #12 copper and placed it within 0.1ft of the outer loop at the bottom.

The base of the whole assembly was placed 10ft above a medium ground.

The results were consistent with most of the calculators found on the web. The loop resonated at 14.02Mhz with a SWR around 1.1. The size of the coupling loop needed to be reduced a bit from the 1/5 diameter. EZNEC has a nice facility for changing the loop sizes to make this easy.

The far field pattern was better than I had expected. The gain at around 25° was just short of 4dBi and the side lobe was down 12dB. Written descriptions I have read led me to believe that a 1/4wave loop would have poorer sidelobes than that. I had not expected to see 4dBi either which compares favorably to a dipole.

Much more puzzling however was the performance at 40M. I changed the tuning capacitor to 110pf and swept the SWR around 7Mhz. Min SWR was in the right frequency range but around 3, too high but fixable with the coupling loop. More disappointing however was the farfield pattern. Probably due to the fact that it is now half the height above ground in fractional wavelengths the antenna is much more of a cloud warmer. This increased upward radiation comes at the expense of directional gain and the sidelobes minima while still present are nearly at ground level providing little suppression to incoming waves at "normal heights. The pattern is basically that of a dome.

The reason that this bothers me is that descriptions of small loops suggest that as the loop size approaches <0.1wavelength the pattern directional performance improves rather than degrades. At 7Mhz this loop is an 1/8 wave and I would think would show improvement.

Any ideas?

jim

5064. Re: Crimp, Clamp or Solder?

Newsgroup: rec.radio.amateur.antenna

If a crimp is done properly, its consistently superior to solder, unless youï¿½re a NASA certified solder person. When I say properly, I mean well designed connectors with the correct crimp tool and tension. Much of the cheap, off shore cable assys with crimp connectors are sub standard and that can give crimp an unwarranted bad name. If you give the same crimp connectors, tools and instructions to a bunch of hams, you will get consistent results. Give the same group solder connectors and various heat implements and the results will vary from excellent to disastrous. Do you really know whatï¿½s inside that PL-259 that you just soldered to a piece of foam dielectric LMR cable? Did the solder gun turn the foam into a solid blob of some new kind of plastic inside the connector? Are you positive the heat didnï¿½t make the center conductor migrate in the dielectric? Did the solder flow up the braid and make a future failure point beyond the connector? I participated in assembling an aircraft wiring harness once (will never do that again) and solder was completely off limits, only crimp connectors could be used. The reasons for crimp were consistency in performance, the ability to audit the crimp tools and peopleï¿½s lives were at stake if something failed.

I recall a story from many years ago - possibly an urban myth - where some guy stuck a pin through a ham's coax feeder and thereby took him off air/blew up his rig etc. Given that RF shorts are a totally different kettle of fish from DC shorts, I'm just wondering how feasible from a technical perspective this reported act of sabotage is.
I'm no expert on transmission lines, but it strikes me that the efficacy of such a stunt depends to a great extent on the point in the line where the pin is inserted as related to the wavelength of the transmitted signal. We all know short and open stubs are used as matching elements at the higher frequencies, so it's implicit that just sticking a pin in anywhere isn't necessarily going to adversely affect the efficiency of an antenna system, unless one hits a node at the frequency of operation. What I mean is, IOW, you won't successfully short out coax at RF unless you stick the pin in at an appropriate point. Of course, I might be full of crap on this one as antennas have never been my strong point. Can anyone enlighten me?

btw: this is for academic discussion only! I've no beef against any amateur and have been one myself for over 20 years.

Talking to myself...

Did a bit more modeling to get rid of the segmentation check warning about the coupling loop having segments too small on 40M. I had to change down to an octal loop for the coupling loop to give me wiggle room on the loop size.

I found that playing with coupling loop diameter and placement distance from the bottom loop interacted and changed the coupling loop impedence presented to the source. In general lowering the loop will make it more capacitive and lower the resistive portion. Making the loop smaller raises the resistive portion and raises the capacitance as well. So I moved it up until the reactance got pretty small then fiddled with the size until the resistance approached 50ohms then moved it up or down to again reduce the reactance. Lots of fiddling. I suspect that indicates a similar level of sensitivity to size and placement in the real world as well.

After playing a bit I got the SWR down to 1.3 or so.

Retuning the capacitor back to the 23pf and retesting at 20M shows a reasonable match (<1.2) there as well.

So it seems that a likely approach for tuning the match loop would be to do it on 40M then test at 20M where it appears to be a bit less critical.

Thanks Richard for digging up an ancient copy of RDFRE.

I do not have ready access to the 'bibles' these days.

I recall the RDFRE as being not altogether a reliable publication. It was useful as a general purpose look-up paper which needed checking particularly when using formula. Approximations were used without saying so as I have found to my cost.

Your quote refers to "Types of antennas normally used" and "for certain configurations". This indicates to me an uncertain range of dimensions. Perhaps some antennas in the range considered were top-capacitance loaded, others were not, some thick and fat, some very slender, some guyed, some not, some with tall base insulators, some not. Even Terman lumps together a range of dimensions and draws conclusions common to the collection.

I recall seeing reference to "Effective Height" in the ancient tomes from 1900 to 1940.

The theoretical effective height of a short receiving vertical above a very good gound was stated to be EXACTLY HALF of actual height. As the actual height approaches 1/4-wavelength the effective height increases (I think) to about 0.64 of actual height which, reassuringly, equals 2/Pi. (I am always reassured when a number like 2/Pi appears in guesswork.)

So the voltage measured between the bottom end of a 1-metre vertical antenna and ground is exactly half of the field strength in volts per metre. And my program has been corrected accordingly to give the correct value for receiver power input.

The 'bibles' refer to "Induced voltage" but the learned authors forgot to state beween which points on the antenna the voltage is referred. This is an open invitation for readers to jump to the wrong conclusions.

Incidentally, the field strength at a distance of 1 Km from a 1000 watt transmitter was always correctly calculated by my program to be 300 millivolts per metre. The calculation does not use the concept of "Effective Height". It uses the concept of power gain relative to isotropic.

Nowhere in the program is the concept of images in the ground, reflections from the ground and half-hemispheres invoked. I was pleased it didn't arise in the discussions. It would have been yet another direction to get bogged down in.

Nice to have your interest.

Reg, G4FGQ.

Could you give a price range and how much real estate you have ? I would
like a 180 ft tower with seperate beams on it for each band but it is much
out of my price range. Also hard to put up a 160 meter dipole on a 1/2 acre
lot. Tell us what kind of antennas you are thinking of .

Inside the coax cable are two conductors carrying current, the inside of the shield and the outside of the center conductor. The current on one of those conductors travels to the antenna, and an equal current returns on the other conductor.

At the point where you insert the pin, the current has two possible paths: it can continue down the cable as it normally does, or it can return to the other conductor via the pin. The fraction which goes each way is determined by the impedance of each path. A pin is electrically very short at frequencies at which the coax can be effectively used, so it has negligible reactance. Assuming that it's making good contact with both the shield and center conductor -- which it might not be -- the resistance will also be small. So it makes a good RF short circuit. Therefore a large fraction of the current will return via the pin rather than going on down the cable. So the first effect will be that it will greatly reduce the amount of power which reaches the antenna to be radiated.

What will happen to the transmitter? That depends on the transmitter and where the pin is inserted. If the cable didn't have any loss and the pin had zero resistance, the transmitter would see a pure reactance. That is, what it would see would look like a pure L or C, with the value and sign depending on the pin's position relative to the transmitter. In practice, the pin will have some resistance and the cable will have some loss, so the transmitter will also see some amount of resistance, the amount again depending on the pin position, as well as the cable loss and pin resistance. I suspect that most modern 100 watt-class solid state transceivers would probably just shut down their output stage and not be permanently damaged, but I'd rather not experiment with my own rig. The result might be more spectacular with a tube type linear with pi network output. But again, it would depend on the design of the transmitter and the particular impedance it sees.

"Pinning" a coax has a long history in the mythos of RF... I've heard stories about it for years, usually involving somebody pinning the coax of an obnoxious CB operator.

>I'm no expert on transmission lines, but it strikes me that the
>efficacy of such a stunt depends to a great extent on the point in the
>line where the pin is inserted as related to the wavelength of the
>transmitted signal.

Well, an effective short at point along the coax is going to cause a complete reflection at that point, and a very high SWR on the line. This may appear to the transmitter as a short, as an open, or as an intermediate resistance with a boatload of reactance, depending on the distance from the transmitter to the short.

A well-designed modern transmitter/amplifier may survive this sort of nasty load well enough, through e.g. voltage and current sensing circuitry which feed back to the bias or ALC circuit, and reduce the power to avoid overcurrent or overvoltage damage, and/or through the use of internally-ballasted RF finals transistors with a big safety margin.

A cheap amplifer (such as many of the "multiple pill" not-so-"linear" amplifiers I see being sold to the CB-cowboy market) could very easily leak out all of its Magic Blue Smoke quite quickly, working into this sort of load.

> We all know short and open stubs are used as
>matching elements at the higher frequencies, so it's implicit that
>just sticking a pin in anywhere isn't necessarily going to adversely
>affect the efficiency of an antenna system, unless one hits a node at
>the frequency of operation.

Not so, I believe. Remember, what you're doing is creating a trivially-short, shorted "stub" across the line. The pin itself will present a low-R, low-Z impedance - most of the power flowing up the line from the transmitter will go into this impedance, and very little

will flow up the remainder of the line to the antenna.

Radiated power will drop very sharply, and the transmitter/amp is
likely to indicate its distress in one way or another.

I leave only this.

At VHF and up it's common to use a shorted 1/4 wave section for
second harmonic suppression at the output. Very effective and dirt
cheap. The finals are not the least bit bothered.

If a short appeared near a 1/4 wave node at operating frequency
it might go unnoticed.

I'm afraid it wouldn't go unnoticed. The transmitter would see an open circuit, instead of the proper load of typically 50 ohms. The effect on the transmitter would be the same as disconnecting the feedline at the transmitter.

I did use the word "might" rather than will.

Actually it depends on the real life characteristics of the short. If
it were a perfect short (in theory) yes. But if there is any varience
from that it's going to be harder to predict. Likely it world look
more like a higher impedence, but not completely. In all likelyhood
the parameter that needs to be know more than any one
its frequency. At 432 it's impact would be very different than say
7.2mhz.

A couple hundred feet is taller than most (all?) cell towers. Nextel used to boast about having the tallest towers, around 110 feet max. Sprint's towers were the shortest before Nextel bought them at around 60 feet. This is why Sprint's signal really sucked balls before Nextel bought them out.

A short across the transmission line will have much the same effect at
432 as it will at 7 mhz.
What you are thinking about is a shorted stub attached to the
transmission line or output of the transmitter. A shorted 1/4 wave
length stub at the operating frequency placed across the transmitter
output will present a high impedance at the operating frequency and
will not be noticed by the transmitter. But at the second harmonic of
the stub it will be a 1/2 wave shorted stub which will present a short

at the output of the transmitter at the 2nd harmonic frequency.

The shorted stub would still allow energy to flow to the antenna normally. But shorting the transmission line would not no matter where it was.

True, but that's not the situation we're dealing with here.

If you place a shorted quarter-wave section directly at the transmitter's terminals, in parallel with the antenna feedline, then the transmitter "sees" the impedance of the feedline (its usual load) in parallel with the impedance of the shorted stub (very high). The net impedance is that of the load (the admittance of the shorted stub is nearly zero) and the transmitter does not "notice" the presence of the shorted stub.

That's not the situation which occurs if the feedline itself is shorted 1/4 waveline towards the load.

In that situation, the *only* thing that the transmitter will see is the shorted quarter-wavelength "stub" between itself and the short. The impedance at the point of the short is nearly zero - it's the impedance of the short itself, in parallel with the impedance of the antenna as seen when looking up the remainder of the feedline. No matter what the antenna's impedance is, the very low impedance of the short itself is going to dominate the parallel combination. The resulting near-zero-ohm combination will be transformed, by the quarter-wavelength distance back to the transmitter, so that it appears as an open circuit to the transmitter.

The transmitter cannot, in effect, "see past the short circuit" to the antenna itself.

The same is true no matter how far up the feedline from the transmitter the short/pin happens to be. At the point of the short, the impedance is going to be nearly zero, and this near-zero impedance will be transformed to some other value on the same very-high-SWR circle (neglecting consideration of feedline loss, of course).

No matter where you pin the coax, the transmitter is going to be unhappy.

>If a short appeared near a 1/4 wave node at operating frequency
>it might go unnoticed.

Different situation, I'm afraid.

If you have an antenna analyzer, try it out for yourself. Take an arbitrary-length section of RG58 with a 50-ohm load at one end and a BNC at the other. Run it into a BNC "T". Out the other leg of the T, run an adjustable length of RG-58 to the antenna analyzer. You ought to measure 50 ohms in this situation.

Now, stick a short directly across the third branch of the T connector ("pinning" the coax, so to speak), and see what your analyzer tells you. It may read high-Z, or low-Z, or intermediate-Z with a lot of reactance... but it'll be a high indicated SWR, and it won't be anywhere near 50+j0.

Then, disconnect the antenna from the "T". The impedance and indicated SWR won't change significantly.

Try changing the length of the RG58 between the "T" and the analyzer. You'll get a different Z value with the short in place (whether the antenna is or is not attached) but it'll still have a really high SWR, no matter what coax length you choose.

One of the reason they don't make them much higher is because, if they
are over a certain height they have to get special permits and have to
notify the FAA.

Ignore the arguing going on here and suffice it to say that you could get a PhD in antenna theory and spend a lifetime experimenting and just begin to have a clear understanding of antennas. That may be exaggerated, but only slightly.

A few general things to keep in mind. Many cell phones work on two different bands, the antenna needs to work on both. When you are interested in signals in a certain direction, in this case out and not up, the longer the antenna the more gain and the more directional it will be. Don't mistake that as an indication that you just want as long as a wire as you can get, it is much more complex than that. For an omni directional antenna where you want to limit the signal to out and not up, stacking several antennas and hooking them all together in some fashion, is one way to do that, but I doubt that any of the little cell phone antennas do that. About the only time you would want an antenna that also send the signal up is if you are communicating with low earth orbit satellites that could be anywhere form the horizon to straight above you. In that case, the antennas start looking more interesting, that a vertical element.

If it were a "perfect" short yes.

For real life the short have real impedence between center conductor
and shield. As frequency goes up a .2" peice of wire accumulates
enough real resistance and reactance to be a factor at high VHF and
uhf.

My favorite filter for 2m is found on the ARRL.com TIS site. it's
made with series and parallel shorted sections operating as tapped
resonant circuits. The stubs are only something like 2" and for 2m
thats about 13" short of 1/4 wave. Just shows what happens when
a transmission line stops being simply that.

>The shorted stub would still allow energy to flow to the antenna

Yes and No. See above.

Car Cellular antennas are longer then this ?

>this was a qustion from my instractor in college

You have been sidetracked into answering the question, when the
premise that "the ideal length of an antenna 1/4 wavelength" is
unsupported and questionable?

On what basis does your instructor make this general assertion?

You could equally be trying to answer the question "If the ideal
length of an antenna is 1/4 Wave length then why Medium Wave broadcast
antennas commonly longer then this?"

What you learn in answering the question will be useful, but you will
also learn that, subject to the meaning of the term "ideal", the
assertion is unfounded, it does not apply in general.

It is equally valid to turn it around and ask that given so many
antennas are not quarter wavelength, is quarter wavelength really
ideal?

Owen

PS: several reasons come to mind why car cellular antennas are not
quarter wave ground plane antenns, they are (over here) multi-band,
they are often so-called ground independent designs (on-glass, gutter
mounts etc) with elevated feed points, they seek higher gain, some are
a metre long for rural coverage, they appeal to buyers who think
bigger is better.

Only if the short is perfect or the frequency is low enough.
Even for shorted stubs doing it right requires a bit of effort
as even a loop at the end causes interesting effects.

>In that situation, the *only* thing that the transmitter will see is
>the shorted quarter-wavelength "stub" between itself and the short.
>The impedance at the point of the short is nearly zero - it's the

Nearly zero is not zero and it's not a constant with frequency.
At 3.5mhz I will agree with you. At 350mhz it's going to show
something different. At 3500mhz, who knows?

>impedance of the short itself, in parallel with the impedance of the
>antenna as seen when looking up the remainder of the feedline. No

However is it parallel or is it some complex reflection of the length
to the antenna.

>reactance... but it'll be a high indicated SWR, and it won't be
>anywhere near 50+j0.

Will it be greater tha say 500+janything? Depends on frequency.

Actually using a tee and doing that creates a working stub that is
tuned in the low microwave region and something reactive below
that. In fact the open Tee at high uhf is also a trouble maker.

>Then, disconnect the antenna from the "T". The impedance and
>indicated SWR won't change significantly.

But t does, depending on frequency and line length on the other side
of the short. Try it for an exact 1/2wave from source to load and pin
at 1/4wave point. the reflected impedences at both ends will be
in play. The pin is only a perfect short at very low frequencies
as you go up the "short" gets "longer" and behaves as a reactance.
It's a complex circuit and there are lumped analogs.

>Try changing the length of the RG58 between the "T" and the analyzer.
>You'll get a different Z value with the short in place (whether the
>antenna is or is not attached) but it'll still have a really high SWR,
>no matter what coax length you choose.

Its easier to vary F than change length. But yes you will see varying
impedences (R+J) all over the map.

I keep saying a perfect short would behave as stated. Most real world components like that pin would be a pain at 3.5mhz and something else at 432mhz.

There is a simple answer, and others have given good advice:

The premis of the question is incorrect. A simple antenna such as a collinear using a quarter wave with a phasing coil and topped with another half wavelength segment will give power gain by modifying the radiation pattern.
That statement should work better than OK.

The assumption may be an error to begin with.
For starters I would say a 5/8 wave antenna may be "more ideal".
If you picture the radiation pattern similar to a balloon with a finite amount of water (the 'power') , the coverage of the antenna can be represented by the shape of the containment.
If you press down on the balloon center with your hand then the circle of coverage will be larger - since we assume the cell towers will be on the same plane as the antenna, you can see that a flat, circular shape will cover more map area than a spherical shape would cover. A 5/8 wave antenna is but one of many types which can exhibit 'gain' by distributing the pattern in more usable directions.
I suspect the antenna the Instructor is referring to is 5/8 wave, and he tried to throw you off with the 'Ideal antenna" statement.
Merry Christmas

Radiators were not lumped together to be covered in common by the equation I quoted. This section continues with individual equations for small loop, and Adcock antennas -- which further I omitted as indicated by the <snip> statement in my post.

Section 2-10 in Kraus' "Antennas," 3rd edition, has much more analysis of effective height. I know you scorn learned authors and their bibles, but perhaps a quick read of this would save you from repeating such investigations to your personal satisfaction, and answer a few of the questions you ask of others here. Maybe you can borrow a copy from your local library.

A suburban lot is a modest sized lot. Ideally I would have only 2 ant. 1 for
HF & one for 2m/220/440. although I see that there are all in ones available
but that would make the HF part, vertically polarized. I can forget 160m. I
know from days of old the QRN was almost intolerable at times with a
vertical. Thanks, Ralph for the post. BTW: I am only interested in
omni-directional at this time.

Do you actually have any hard data on this Paul? Not that I dont believe you, just would like to know how many dB we are talking about. "sucked" doesnt translate very well...

I was surprised when I visited the US for the first time how much higher the cell towers were compared to Australia's. From what I understand though cell use in Australia (per unit pop) topped the world for a while and it was undesirable to have high towers because the larger cell size meant co-cell interference was more likely. Towers and antennas then ended up on shorter towers and building sides to allow for the higher density of users.

Towers in rural areas were of course a lot higher but they had an upper limit when you factored in the 32km limit for GSM systems. It was often frustrating when travelling in thee areas to see 3-4 cells sites in strong signal range but unable to make/receive calls because of that max distance restriction.

Cheers Bob W5/VK2YQA

Hello:

Anyone have any strong opinions regarding PolyPhaser, ICE, and Alpha Delta Lightning Arresters ?

Would be for a receive only antenna.

Do I want the dc blocked variety, or doesn't it matter for receive only (0.5 to 30 MHz) ?

Thanks,
Bob

Depending on the size of your lot, a dipole for 80 or 40 is pretty
easy. I you make it an inverted V, that will give it a more
omnidirecitonal pattern, if that is what you want.

If you can put up a dipole, you may want to try a dipole, either trapped, or fed with open wire. An off center fed antenna is not bad either. You may have trouble getting enough wire in the ground for a vertical to work very well. Putting down 20 to 100 ground wires is more trouble than I care for. At low heights the dipoles, especially if inverted V types have a very broad pattern, almost omni-directiona. One thing about the dipoles is you can buy a bunch of wire at the local store for a small price. If you don't like it, you have not spent the $ 200-300 for the verticals.

For vhf FM work most any of the dual band verticals seem to be ok. I have not looked at any that cover the 220 band also. It may be hard to find a single antenna that will do 144/220/440 . I usually work ssb on the vhf bands and do very little on the repeaters so that has not been much of an issue with me. SSB usually requires a horizontal antenna as that is what most are using and you will take a big (around 20 db) hit going from one to the other.

I have at 2400mhz too! Down around DC (sub 30mhz) your "pin"
is a short and the effects are mostly (though measurable) a shorted
coax with all the effects as expected. As you get up there in
frequency the "short" as described doesn't behave as it did at DC.

The problem is similar to another thread concerning real world
components where the discussion finally recognized that like other
real world components a short is not always what it may look like.

It's really a question of the problem domain - that is, what are the
frequencies involved, and what are the sizes of the feedline and the
"width" of the shorting bar/pin? Allison and I have been talking
about rather different sets of test conditions. I think we're
actually in "violent agreement" about what actually goes on.

At upper-UHF and microwave frequencies, I agree that Allison is correct.
The length of the pin is a significant fraction of a wavelength, and
it thus does not behave as a true short circuit - rather, it's an
inductor of significant value shunted across the transmission line.
At these frequencies, in this problem domain, you have to consider the
shunt combination of two non-zero impedances. "Shorting" the feedline
with this 'straight pin' inductor will probably have a significant
effect on the impedance seen by the transmitter, but it won't be as
simple as I had portrayed.

At HF (and, I think, VHF up through the 2-meter frequency range) a
shorting pin of perhaps 1/4" in length is a negligible fraction of a
wavelength long. Whatever small amount of inductance it introduces
will have a reactive impedance whose magnitude is far below that of
the 50-ohm load, and its very high admittance will swamp the lower
admittance of the load. Hence, the load impedance will be of
negligible importance in deciding what the transmitter "sees" at these

frequencies, under these conditions... the transmitter "sees" only the impedance of the short itself, transformed by however much line is between transmitter and short.

If I can find a scrap BNC male connector, and make a shorting-plug out of it, I'll run the coax-and-T experiment I suggested, and post some actual numbers for the systems's behavior at those frequencies I can coerce out of my MFJ-269.

I notice it is a 45-foot end-fed wire. That would make it 1/4-wave
long at about 5.2 Mhz. They claim it is optimally designed for
reception from 1 to 30 Mhz. Not sure how thay arrived at that claim.
It should work fine, but just about any random length wire will work
if you have a decent receiver :-)

Hi,
I have recently put a cordless phone on my boat. The boat is docked
and I would like the handheld to ring when I'm on the marina.The boat
is all aluminum and limits the distance the phone base will transmit
to the handheld. The distance is down to about 1/3. If it was only
limited to 2/3 of it's normal range I wouldn't have any problem!
I would like to put an antenna outside the boat to get the range up.
Any suggestions on how to couple the signal to an external antenna?
I have a picture on abse with the subjuct "915 Mhz antenna" See the
antenna with the coil, (ignore the short one, the is a 5.8Ghz antenna)
Any chance the antenna is 50ohm and I could remove it, attach a coax
and put the antenna back on the other end? :-/

Mike

Please reference "Baluns: What They Do and How They Do It" by W7EL.
VSWR causes impedance transformation. Impedance transformation
varies the impedance. Baluns work better with some impedances than
they do with others. Therefore, VSWR can cause balun malfunction
accompanied by feedline radiation. All it takes is one time. And a
possible cause is not necessarily a probable cause.

There is nothing to suggest that you will be injured every time you

From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <J8KdnYXx0dnwvjLeRVn-uQ@comcast.com>
Source record: 66055

The programs vertload.exe and loadcoil.exe produce similar results for radiation efficiency and radiation resistance. In both cases the antenna is configured as a 6 meter vertical with a 10 cm long, 75 mm diameter coil in the middle.

However the coil dimensions or the input impedance do not match between the programs. Vertload predicts a 50 turn coil with an ATU capacitor of 1289 pf. While loadcoil predicts a 31 turn coil and 0 feedpoint reactance.

What causes the difference? Which one is the better model?

Thanks - Dan kb0qil

Your example depends on the (mis)behaviour of a component (the balun)
external to the feedline as a vital link in the asserted relationship
between high VSWR and feedline radiation (both properties of the
feedline itself).

As you describe it the balun was not suited to the application, and it
is the interaction of the unsuited balun in the whole topology that
gives rise to feedline radiation.

In addressing the suitability issue, you could:
- change the environment external to the balun until the balun was
suitable; or
- replace the balun with one that suits the external environment.

If the balun were replaced with a balun that was effective, then
feedline radiation would be reduced sufficiently, without needing to
reduce the high VSWR on the feedline.

Excessive feedline radiation is not a necessary outcome of high VSWR,
high VSWR does not, of itself, cause feedline radiation.

If high VSWR does not, of itself, cause excessive feedline radiation,
then finding the root cause of feedline radiation means looking beyond
the myth that high VSWR feedlines radiate.

>If I can find a scrap BNC male connector, and make a shorting-plug out
>of it, I'll run the coax-and-T experiment I suggested, and post some
>actual numbers for the systems's behavior at those frequencies I can
>coerce out of my MFJ-269.

OK, I ran the test, and the results are pretty much as I had anticipated. Although the test arrangement and gear isn't lab-standard, I think it's good enough to confirm the basic principles.

Test equipment: MFJ-259 antenna analyzer, with an N-to-BNC adapter.

Transmission line and load: 12' length of RG-58 coax, with a 50-ohm Ethernet terminator attached to the end.

Shorting insertion: an additional 6' length of RG-58, with a couple of BNC "T" adapters, which can be inserted between the analyzer and the T-line-and-load. If the shorting plug is inserted it'll be 6' from the analyzer and 12' from the load.

Short circuit: a male BNC plug, with a short inserted between center pin and shell as far down inside the shell as possible.

First test: check quality of T-line and load, using only the 12' section of RG-58 between analyzer and load. Note that the Imag(load) numbers do not indicate the sign of the reactance... the MFJ won't do that, alas.

Frequency Real(load) Imag(load) Indicated SWR
2.5 52 4 1.0
5 58 6 1.2
10 57 7 1.2
15 49 1 1.0
20 56 6 1.1
50 54 2 1.1
144 51 4 1.0
166 59 8 1.2
440 1.4

Impression: either the RG-58 or the Ethernet terminator isn't exactly 50 ohms (not unexpected) or the MFJ's calibration isn't perfect (likewise) but the figures are good enough to let us draw some reasonable conclusions.

Second test: insert the 6' RG-58 and its T connectors between the analyzer and the 12' section. See how much this additional length of line, and the parasitics of the T connectors, affect the load and SWR.

Frequency Real(load) Imag(load) Indicated SWR
2.5 54 4 1.1
5 59 5 1.2
10 50 10 1.2
15 49 1 1.0
20 51 8 1.1
50 48 5 1.1
144 50 4 1.0
166 40 2 1.2
440 1.1

Impression: the measured values change a bit, but the SWRs are close or identical (save for the 440 measurement). The additional length of line, and the parasitics from the T connectors, are shifting things around a bit (especially at 440)... not unexpected.

Third test: connect the shorting plug to one of the T connectors. See what "pinning the line" does to the analyzer's view of the load.

Frequency Real(load) Imag(load) Indicated SWR
2.5 0 6 >31
5 0 12 >31
10 1 26 >31
15 1 43 >31
20 2 70 >31
50 0 44 28.7
144 7 33 15.4
166 166 353 13.0
440 >5

Impression: yeah, that looks like a short circuit, transformed via a feedline. Nothing close to a 50-ohm-resistive load shows up at any of the test frequencies.

Fourth test: disconnect the 50-ohm load from the end of the 12' line, creating an abrupt change in the load impedance. See what this does to the figures from the third test - how much of the antenna load change gets back "around" the short?

Frequency Real(load) Imag(load) Indicated SWR
2.5 0 6 >31
5 0 12 >31
10 1 25 >31
15 1 43 >31
20 2 70 >31
50 6 44 29.0
144 6 30 18.5
166 133 317 14.1
440 >5

Impression: changing the antenna load from 50-ohms-resistive to near-infinite made a slight change in the impedance seen by the analyzer, but not much at all at any frequency. The presence of the

short circuit 6 feet from the analuzer is still dominating the load that the analyzer "sees".

Special-distance test: with the short, and the 50-ohm load both in place, sweep the analyzer frequency around the ranges at which the analyzer-to-short distance is around 1/4 and 1/2 wavelength. See if we can "see past" the short under these conditions.

Measurements: with the short circuit in place, and a 50-ohm load at the end of the 12' line, an impedance peak (Z>1500 ohms) is noted when sweeping between 32.14 MHz and 32.94 MHz. An impedance minimum (Real(load) of 2-3 ohms, Imag(load) of 0 ohms) is noted between 65.7 MHz and 65.85 MHz. The indicated SWR remains high (22 or above) at all frequencies between the impedance maximum and impedance minimum... there's no point at which the load resembles anything like "50 ohms resistive, little reactive component".

Removing the 50-ohm load, and thus open-circuiting the antenna feedline, has no significant effect on the impedance as seen at the quarter-wavelength maximum, at the half-wavelength minimum, or at points in between.

Impression: we cannot "see past" the short circuit, no matter whether it's a quarter-wavelength from the transmitter, a half-wavelength, or some distance in between these two. The analyzer "sees" only what would be expected for a short circuit, transformed by 6' of coax.

Short-circuit quality test: measure impedance of the shorted BNC plug.

At 16 MHz and below, the MFJ-269 shows it as 0+0j. Above 16 MHz, some reactance shows up... 2 ohms at 28 MHz, 3 ohms at 42 MHz, 4 ohms and 55 MHz, 8 ohms at 112 MHz, 10 ohms at 144 MHz, 12 ohms at 169 MHz. The inductance of the shorted plug itself, and/or the length of the N-to-BNC adapter on the analyzer, is having some effect. SWR remains unreadably high: >31 up through VHF and >5 on 440. It's not the highest-quality "short circuit" in the world, for certain, but at HF and VHF it's close enough for our purposes here.

So... what do I conclude from this?

I conclude that at HF and VHF frequencies, if you accidentally short your transmitter-to-antenna coaxial feedline (with a pin, nail, or a loose strand of coax braid which "gets loose" inside a connector), you're going to present your transmitter with an unrealistic load (high, low, or nastily reactive) and that the power flow up the feedline is going to stop at the short circuit.

Since no "short circuit" in the real world is going to have 0+0j impedance, this isn't *absolutely* true, but you can probably consider it to be *practically* true and correct at these frequencies, with this sort of shorting.

I further conclude that with respect to the above, there's no 'magic' about shorts which happen to occur at a quarter-wavelength distance from the transmitter. In this situation, the transmitter will 'see' something which behaves like a quarter-wavelength shorted stub... the load further up the transmission line at the antenna remains 'invisible' to the transmitter.

At high-UHF and SHF/microwave frequencies, where a direct "short" is likely to be a significant fraction of a wavelength, then the additional reactance of the "short" will certainly affect how the undesired connection affects what the transmitter "sees". It may hurt, or help (helping to "tune out" reactance from the antenna itself), or may be completely invisible. Allison is entirely correct on this point, under these particular conditions.

Key thing is somewhere bwtween 144 and 440mhz something is happening
that is not a short circuit but, not tested either. Also a SWR of 5

while high tells us that collective losses (RG58) and instrument
limitations are hiding information.

Definatly at HF, likely at low VHF. As we get to 300mhz we don't
know but, likely not good at all.

>Since no "short circuit" in the real world is going to have 0+0j

We do agree, if the conditions are unspecified are also likely
meaningless. If the conditions are specified we will likely agree.
I know it sounds picky to no end but it's about those little second
and third order things often ignored and renders answers that are

more lore than tested fact.

Allison

It can be either way.

If you choose to use separate transmitters the demands on antenna
bandwidth are greatly reduced.

Thanks John, my IC-706 will receive the TV frequencies, but since I have never heard any audio, I assumed the audio and video were mixed to an IF frequency and then mixed to the TV frequency. (I have a reference book on TV but haven't looked at it in a long time).

>If the common folk play their cards right BPL can't compete with
>anyone anywhere. If rollout is inevitable it's time (past time

The PUCs want it for grid control and monitoring. The BPL marketers
have made it look like they can do that (which they can) plus have an
revenue stream from their costomers.

>actually) to go to the PUC and ask that everything related to BPL only
>be paid for from revenue gained from BPL. No shifting of revenue from
>power sales to support BPL - strictly separate. Also ask that service

They will just state they are running the service for monitoring and
control anyway so it'll be handy if any one wants to sign up.

>be provided promptly to anyone asking for it and everyone at the same
>price regardless of whether in a large city or one with a population
>of 22 at the end of 150 miles of dead-end power line. After all, BPL
>promises high speed Internet access to EVERYONE and you can be sure

Some implented forms of BPL can't even deliver high speed with very
many customers before running into packet collisions which means wider
bandwidth or slower service.

>that at some point that was said. Hold them to it now, not 20 years
>from now. The result? BPL economics absolutely cannot support the
>promises made for it. If they have to fulfill the promises it's dead
>before it starts.

If they can be held off just two years regular broad band will be
widely available and cheaper. Rather than out in the country where
it's expensive to implement, they are finding the prime candidate are
offices and apartment buildings. OTOH once those offices and

apartments are up and running I wonder what kind of track record they'll have? Add a few real time gamers, VoIP, and some streaming video.

Harry E. Landsberg, Jr., CIA Maltese Falcon: Kennedy assassination,
IRAN/CONTRA, UFO's

My late father, Harry E. Landsberg, Jr. is apparently one of the 35 CIA
Officers memorialized on the north wall of the Original Headquarters
Building lobby whose "names ... must remain secret, even in death."

Please see:

http://www.angelfire.com/journal2/landsbergphotos2/maltese_falcon_search_terms_maltese_falcon_cia_dot_gov.jpg

taking note of the search terms "maltese+falcon."

Then:

http://www.angelfire.com/journal2/landsbergphotos2/maltese_falcon_cia_dot_gov_memorial_wall.jpg

and

http://www.angelfire.com/journal2/landsbergphotos2/maltese_falcon_cia_dot_gov_memorial_wall_2.jpg

---

I was discredited as being mentally ill in 1981 and again in 1985. As
a result I was motivated to research family matters.

In 2004 I learned that my husband, Richard Hanning, Jr., was a
Marine/covert operator assigned to me. We met in 1985 and I knew I was
a target when I met him. I just didn't know I was his target.

We are divorced. My life has been in danger and I have been revealing
information about my family and their associates as a result.

Please see:

"Harry E. Landsberg, Jr. -- resemblance to man in photo with Specter"
http://home.earthlink.net/~lhann10243/index.html

and

"IRAN/CONTRA: Fleming O. Landsberg, Fleming Landsberg, U.S. Ordinance
[sic] Inc."
http://home.earthlink.net/~lhann10243/id85.html

and

"Landsbergs and Maddens -- Mirror" (UFO's)
http://www.angelfire.com/journal2/landsbergphotos/Landsbergs_and_Maddens_mirror.html

---

I am a survivor of satanic ritual abuse and mind control.

Please see:

"The Love Game"
http://home.earthlink.net/~sammark4/id2.html

and

"Scars and other signs of mind control"
http://home.earthlink.net/~sammark4/id5.html

My legal mother, Donna Jean Volkmer Landsberg, worked as secretary to
the Undersecretary of the Navy in the 1940's, likely James Forrestal.

He died under mysterious circumstances. Please see:

"The Death of James Forrestal" by Richard M. Dolan
http://keyholepublishing.com/Death%20of%20James%20Forrestal.htm

---

I had a vision of Donna as a three-headed bird (black heads.)

I was searching for photos of Vanessa Redgrave and found this photo
which was similar to the bird in my vision:

http://www.angelfire.com/journal2/landsbergphotos2/donnas_bird_head_more_like_this.jpg

Then searching on "Maltese Falcon" I came across "The Virtual Tour of
the CIA:"

http://images.google.com/imgres?imgurl=http://www.cia.gov/cia/information/
tour/83stars_lg.jpg&imgrefurl=http://www.cia.gov/cia/information/tour/
stars.html&h=465&w=600&sz=184&tbnid=fQ8WESE-YHkpWM:&tbnh=103&tbnw
=133&hl=en&start=130&prev=/images%3Fq%3D%2522maltese%2Bfalcon
%2522%26start%3D120%26svnum%3D10%26hl%3Den%26lr%3D%26sa%3DN

or

http://www.cia.gov/cia/information/tour/stars.html

There is no mention of the words "Maltese Falcon" on the page.

There was a Divine Intervention in late 2003 and I have been protected
as I have been enduring harassment in the astral plane.

If the meter is misapplied, it's misapplied. If my transmitter is designed to operate optimally into a 300 ohm load and I use an "SWR" meter calibrated to 50 ohms, it's not going to do any better job indicating proper transmitter matching than indicating SWR on a 300 ohm line.

I will continue happily to call my SWR meter an SWR meter, and know enough about what's going on inside it to apply it appropriately--whether it's to the task of giving me an indication of SWR on a transmission line or the task of indicating proper loading on a source.

I suppose there are many who will continue to happily call them SWR meters and NOT understand how to properly apply them. I'd much rather work on educating them to understand how the meter works and how to apply it properly than to insist they call it by some other name. I've been at the task since B.R.E.

But of course, not everyone sees it that way.

Cheers--and Merry Christmas,
Tom

Fred, is the correct answer because although analogue TV sound in
frequency modulated on a sub carrier of the composite signal, the sub
carrier is not transmitted in the "commercial FM band".

Cecil's IC-706 may not cover the entire TV broadcast bands, he only
asked why, when he can receive the commercial fm band just fine, can
he not receive TV sound in general.

Cecil probably knows the answer.

Owen

5126. No link attitude!

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-26 04:22:04 UTC
From: n9zle <NoSpam@nospam.com>
Message-ID: <MdKrf.37455$dO2.5960@newssvr29.news.prodigy.net>
Source record: 66073

No link attitude!

http://www.n9zle.com/forum/

What is it with this no-link to other site attitude?
Years ago when the internet was in its infancy just about any site would add your site as a link from theirs. In return you would do the same. But now it has come to NO-LINKS. Not even in the forums. I have had a website located on tripod for about 9 years over those nine years I had a link to qrz dot com That site received over a million hits. And many users went from that site to qrz and on-to Icomamerica dot com. I have always supported Icom. They have never given a link on their site to mine. I have always supported qrz. But of course he(AA7BQ) never put a link on his site to mine. Well you may say that "I never asked". And that is true. But recently I have noticed he has been deleting my posts. ALL OF THEM. He never contacted me telling me why. AA7BQ just deleted them. I build CIV cables and sell a few of them every week to amateur operators who want them. When I posted one on his site. I found he deleted the post soon after it was placed there.

My beliefs are.
1. QRZ AKA AA7BQ no longer has the amateur radio attitude.
2. AA7BQ has gone fully commercial but calls his site "The Ham Radio Super Site"
3. AA7BQ does not have your best interest in mind.

I can also prove what I am writing here.
For one if he claims he is nothing but a commercial site then why does he ask for donations?
If he is not a commercial site than why will he not allow me to post my CIV cables on his site?

That takes care of number 2
Now for number 1 and 3. If some one knows the truth about something but keeps it from you he is a liar.
No mater how you put it, he is a liar. On the QRZ site Fred is there to help you renew your license. Or so he leads you to believe so. He charges you for it. Mr. Lloyd has never revealed it to any amateurs that you can renew your license or do an address change at the fcc.gov web site for FREE. Yes TOTAL FREE at the FCC web site.
The forms at the FCC web site or no harder to fill out than his.

His CD. He charges 24.95 plus tax and shipping. On that CD is data he obtained from the FCC and got it for FREE, he sales it to you. Also he has software, created by programmers like MYSELF. And MODS that have been made available from the manufactures and other HAMS like ME! I have been contributing to Amateur Radio community for greater than 10 years, and have

received very little for software I created. Never complained when it was copied. I have performed and created several of the MODS for various transceivers. Never asked a penny for it. I never commercialized HAM RADIO. And NEVER took money from some one for something they could get FREE else where.

I am sure many of you would like to ask me "what I am going to do about it?" Here is my answer.

I have created an open forum on my web site http://www.n9zle.com/forum/

There you can post a link to your own site even if it is a commercial site. You can post any ham radio equipment you have for sell on the site.

You can do a callsign lookup at my site from the FCC database, not that stupid qrz thing.
I will soon put together an open source database that I will sell for the price of the CD plus the true cost of shipping. About two bucks total. Once you install the database on your system, you will be able to download updates for FREE. I will make drivers available to programmers to access the database in several different languages and operating systems. I will also attempt to make the database available on the internet for FREE to download.

I only ask for a little help from other HAMS like myself. I need a few elmers that are willing to moderate some of the forums. It is easy and you will find it fun. If you have any suggestions on new forums or sections please logon to my site and make a post.

> Cecil probably knows the answer.

Actually, I don't. My IC-706 certainly covers 60-66 MHz which
is channel 3 in College Station, TX. I jumped to the conclusion
that since I couldn't hear WFM audio anywhere on that band, that
the audio wasn't detectable until down-converted to the
intercarrier. It is possible that I hit some dead air time and
gave up too soon.

I just cracked open my TV reference book and it indicates there
are two ways to detect the sound, split IF reception and intercarrier
reception. What now seems most likely is that I didn't tune high
enough up to the 65.75 MHz sound carrier frequency or if I did
tune that high, I hit some dead air time with no modulation.

Next time I'm over there, I will try again.

For what it's worth, I'm able to use my Kenwood TS-2000 to tune in the audio carrier of our local Channel 2 station. According to my cheat sheet, 2's video carrier is at 55.25, with audio carrier 4.5 MHz higher... hence 59.75 MHz. It seems to tune in best on my radio at 59.745.

Your channel 3 audio carrier ought to be at 61.25 + 4.5 = 65.75 MHz.

I don't have my service monitor handy so I can't tell for certain what the peak FM carrier deviation is, but it's definitely broad enough to cause serious distortion on my TS-2000 (which is set up for ham FM deviations of around 5 KHz). My recollection is that TV audio carrier deviation is similar to that of commercial FM broadcasts.

It's possible that your IC-706 isn't willing/able to lock onto a carrier with such a high deviation, perhaps? or perhaps it needs to be switched manually to a "wide FM" mode to do so in this frequency range?

The point of minimum Z (that is, minimum magnitude of Z) will probably be close to resonance. Resonance is the frequency at which the reactance is zero. In a typical antenna near resonance, the reactance changes much faster than resistance with frequency. This causes the magnitude of the impedance, and the SWR, to be minimum near the resonant frequency. It should be true for the antennas you asked about. It isn't true for all antennas, however.

Tell me why can't one place stock and sale all the connectors I want?
What a pain. I'm curious if someone knows of an online source that
stocks all of the following

Cable Ends
N Male crimp for LMR 240
N Female crimp for LMR 240
N Male crimp for LMR 400
N Female crimp for LMR 400
N Male crimp for LMR 600
N Female crimp for LMR 600
SMA Male Crimp for LMR 240
SMA Female Bulkhead Crimp for LMR 240

Adapters
N Male to UHF Female
N Female to UHF Male
N Male to SMA Female

BTW, who is the inept clueless moron that decided UHF Female should be
called SO-239 and UHF Male should be called PL-259? And why do people
still call them that? While I'm ranting, they should rename it to VHF
or maybe even HF, it certainly shouldn't be called a UHF connector.

USA DOD and NASA [DOD STD 454 et al] specifications insist that both a secure and stable mechanical connection, crimp or clamp, be used for strength, temperature and fatigue stability; and, that solder or weld be used, occassion appropriate, for electrical connectivity.

In the typical amateur usage that would include a strain relief [crimp or clamp] for those connections where a mechanical stress [bend or weight] and solder.

Isn't it necessary to define an impedance against which the antenna input impedance and SWR is referenced? It may not always be 50 ohms or some other "standard" impedance.

For example, a self-resonant 1/2-wave dipole in free space has an input Z of about 65 +j0 ohms, but will not constitute a 1:1 SWR to an r-f system that otherwise is 50 ohms, even though antenna reactance is zero.

SWR is the dimensionless ratio of two voltages, a maximum and a minimum, which may be measured along a transmission line, spaced apart by 1/4-wavelength of line.

Or it can be the ratio of two similarly displaced currents.

It is fully described without reference to line impedance, source impedance, terminating impedance, line length, or where the max and min volts are located.

Incidentally, before it can be used for anything, extra information is needed.

That just strikes me as plain stoopid. At MW, such filtering would be
far better achieved by lumped elements. A quarter wave stub at such
frequencies appears impractical, unwieldy and rather expensive!

Yes, and in typical configuration it is an electrical 1/4-wave coaxial section connected in parallel with both conductors of the main transmission line. It does not terminate the main transmission line, so this application/example is not very relevant to the "pin through the coax" question of the OP. And it would not result in a dead short at the carrier frequency, no matter where it is located in the output system. Some FM broadcast antennas also include them to supply a DC short from inner to outer conductors of the antenna coax to provide some protection from lightning.

A 1/4-wave shorted stub is used at frequencies as low as the MW broadcast band. The need there is to add a deep notch at stations whose 2nd harmonic falls in the broadcast band. This stub is used to add to the attenuation of the already compliant 2nd harmonic level coming out of the tx, but which, without the stub can be heard on broadcast receivers within a short distance from the broadcast antenna site. WJR (760 kHz) is one station using this technique.

SWR may be calculated as (A+B)/(A-B), where A & B are square roots of expressions containing both the complex load impedance, and the reference impedance against which the SWR is referred.

Or (|Vfor|+|Vref|)/(|Vfor|-|Vref|)

> Or it can be the ratio of two similarly displaced currents.

Or (|Ifor|+|Iref|)/(|Ifor|-|Iref|)

Or at an (antenna feedpoint) impedance of (R +/- jX) and a resistive Z0

SQRT[(R+Z0)^2+X^2] + SQRT[(R-Z0)^2+X^2] divided by
SQRT[(R+Z0)^2+X^2] - SQRT[(R-Z0)^2+X^2]

Or (1+rho)/(1-rho) if the reflection coefficient is known.

Or it can be [SQRT(Pfor)+SQRT(Pref)]/[SQRT(Pfor)-SQRT(Pref)]
which is the indirect one a typical MFJ dual-needle SWR meter
uses.

I didn't even see that there were two numbers. These part numbers
were originally in a list of many variations in military part numbers.
Perhaps these two examples were just the most popular ones in that
list of variations.

TV aural uses a separate transmitter from TV visual, because the visual amplifier in a TV tx is not linear enough to amplify both the aural and visual waveforms while maintaining r-f intermods sufficiently low (to FCC spec). The aural and visual signals are combined with mutual isolation of the txs, and radiated by a single antenna, typically.

In an emergency, TV stations sometimes combine A&V at exciter level and pipe them through the visual PA, which is operated at reduced power to minimize r-f intermods. Typically the TV station is not meeting spec then, however.

> If you choose to use separate transmitters the demands
> on antenna bandwidth are greatly reduced.

Reducing antenna bandwidth needed also would require separate antenna systems for the aural and visual transmitters. That is done, occasionally - but not often. This doesn't reduce the bandwidth needed by the visual tx by very much, however. Generally it's more cost-effective to use a single antenna to radiate both A&V.

Source record: 66100

US TV aural is frequency modulated, with +/-25 kHz deviation defined as 100% modulation. Pre-emphasis of 75 microseconds is applied to program audio.

It is transmitted as a discrete r-f waveform about 250 kHz below the upper edge of the TV channel. TV receivers typically demodulate it using an FM detector tuned to the 4.5 MHz intercarrier product present in the output signal of its video detector. Therefore if the TV visual carrier (only) goes off the air, no audio will be heard at the TV set, either.

Any communications-type receiver capable of tuning to, and demodulating the TV aural carrier will enable listening to it. Even some little "pocket" AM/FM radio receivers have that ability.

It also provides a low-impedance and fairly wideband path to ground for the insulated, series-fed tower used by most broadcast stations -- which drains off any static charges that may collect on the tower, and so reduces the probability of lightning strikes.

Lumped elements are less effective at this.

>
> Your channel 3 audio carrier ought to be at 61.25 + 4.5 = 65.75 MHz.

The normal video carrier frequency for US TV stations is 1.25 MHz above the low frequency end of the channel, and the audio carrier frequency is 4.5 MHz higher than that. But some station assignments specify that the video carrier should be a small number of kHz above or below the frequency described above, with the audio carrier still 4.5 MHz above the (displaced) video carrier so that when the TV receiver is properly (mis)tuned, both carriers will be converted to the expected intermediate frequencies. Perhaps your channel 2 station has been moved downhill 5 kHz. In any case the +/- 25 kHz deviation for 100% modulation would make the audio sound pretty ugly on a narrow band ham receiver.

You might want to look into a multiband Hexbeam. A 10, 15 and 20 meter multiband Hexbeam would weigh in at under 15-20 pounds and less than 20 feet in diameter. Optimum height is 30 feet and a medium size TV rotor will handle one. Spiderbeams are similar but a little larger spacewise.

==========
Hello Dan,

Both programs will accept input parameters for a short coil-loaded
resonant vertical above ground. But they are designed to output
different computed parameters and do not use exactly the same models
or calculating methods.

The input parameters are stated in different forms and when comparing
one program with the other it is important to ensure the correct
antenna dimensions are entered. In particular, the overall heights
should be the same and the centre of the loading coil must be at the
same height above ground on both models.

I am unable to check your figures. You have given me insufficient
information. The resonant frequency is essential.

But to satisfy myself there is not a bug I have modelled the following
antenna using both programs -

Using program LOADCOIL

Overall height = 6 metres.
Mast diameter = 10 mm.
Rod diameter = 5 mm.
Coil Length = 100 mm.
Coil Diameter = 75 mm.

Location of coil center = 59.5% of overall height.
Ground loss resistance = 5 ohms.
Resonant frequency = 3.8 MHz.

Using program VERTLOAD

Mast height = 3.52 metres.
Mast diameter = 10 mm.
Coil length = 0.1 metres.
Coil diameter = 75 mm.
Rod length = 2.38 metres.
Rod diameter = 5 mm.
Ground loss resistance = 5 ohms.
Resonant frequency = 3.8 MHz.

The height of the coil above ground is that which maximises radiating
efficiency for a given physical size of coil.

As a check on agreement between the two programs, compare the few
computed output parameters which are common to both -

Programs VERTLOAD and LOADCOIL

Radiation resistances = 5.6 and 5.1 ohms.
Feedpoint resistances = 12 and 14 ohms.
Efficiencies = 47% and 35.1%.
Turns on coil = 43 and 40 turns.
Coil wire diameters, 1.63 and 1.64 mm.

The difference between efficiencies is 1.3 dB.

I think the some of the differences can be due to program Vertload
neglecting the increase in effective coil diameter due to being wound
on a former of nominal diameter.

For different frequencies and antenna heights there will be different
sets of differences but of similar magnitudes.

The more accurate program is probably Loadcoil because it was
specially designed to find maximum efficiency by sliding the coil up
and down the antenna. The effect of the length of the coil on
radiation resistance is probably more accurately taken into account.
It is also a more recent program.

In practice there's nothing to choose between them. The uncertainty
in results will be controlled by the uncertainty in input data,
particularly the uncertainty in ground loss resistance.

Reg, G4FGQ.

5161. measurement error or bad coax??

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-26 21:43:05 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <N7ednVZ2xdN3_i3enZ2dnUVZ_vydnZ2d@comcast.com>
Source record: 66108

I have a section of air core Beldin coax, with the center feed separated by a single wind of plastic insulator. The section is about 65 meters long. I added enough RG58 to the feed end to get a full wave length. I then measured the impedance using aa Autek analyzer. It read 30 Ohms.

The coaxpair program predicts for coax with a loss of about 10 db per km an impedance of about 11.5 Ohms. The cable should be better then this.

Is this difference leaky or bad coax? Is it reasonable to assume water in the cable? If it is water is there a practical way to get it out?

Thanks - Dan

Thank you very much.

Can you speak to the calculated ATU value in VertLoad? Is it the value to match to a 50 Ohm coax?

One of the program set simulates a dipole with a base coil centered between the elements. Is there a program to simulate a dipole with each of the arms center loaded? I was trying to approximate this by vertload/loadcoil simulations. They should be pretty close.

Thanks - Dan kb0qil

Dan, you are a master of asking questions with partial / unreliable
information... and you have done it again!

Doesn't the Belden cable have a legible type marking?

How much RG58 did you add? (Why?)

What frequency did you make the measurement?

Was it 30+j0?

What was the objective of the measurement? If it was to determine
cable loss, does the Autek book give you a procedure for doing that?

Owen

65.75 is the magic frequency. It does appear the WFM mode can not be used on this frequency on the 706 MKIIG I have. In the FM position, while distorted it is copyable. The radio shows WFM mode, but it certainly isn't in the wide mode.

Now I have to get in the circuitry and see why the WFM is not operable on this band.

My original problem was with an original IC-706 which I sold.
I'm now mobile with an IC-706MKII with DSP. But my mode switch
switches from FM to AM to FM ... and never shows WFM at all,
not even when tuned to 88-108 MHz so commercial FM or TV is not
worth listening to. I have a Sony Walkman that does receive VHF
TV audio and my CCRadio+ does also.

Three additional questions:

What was connected to the far end of the coax when you made the measurement?

How did you determine that the combination cable was one wavelength long?

What was the angle of the impedance, or the resistive and reactive (R
and X) parts?

Right you are.
Like I said - using a 5/8 wave vertical flattens out the "doughnut of propogation."
And using two - back-to-back as a dipole will exhibit gain as well - over a dipole.

Roy, thanks.

1. The far end was open.

2. I used an 8405a and a directional coupler connected in reverse. I zeroed the 8405a open stub between the driven signal and the reflected signal. I then added a coax segment and the feedline to bring the the 8405a back to near zero deflection at a frequency near the frequency of interest. I then tweaked the frequency to re-zero the reflected signal.

3. I believe the reading was 30R and 0j. The intention was to tune frequency and the meter to one electrical wave length and reach zero x.

>cable? If it is water is there a practical way to get it out?
>

The hints in this guessing game are:
- this might be the popular Belden 9913, lets proceed on that
assumption;
- that 65m is less than a full wave, so the frequency of the test must
less than 3.87MHz;
- the loss at the frequency of interest might be 10dB/km, implies 7MHz
for 9913 (MLL for 9913 at 3.875MHz is around 7.4dB, and less at
~3.6MHz);

Bzzzt... does not compute, inconsistent input data.

Some trivia:

The input resistance to a 65m shorted stub of 9913 at its half wave
resonance at 3.875MHz should be around 2.8+j0 ohms.

The input resistance to a 65m open stub of 9913 at its half wave
resonance at 3.875MHz should be around 900+j0 ohms.

It is anyone's guess what adding an unspecified piece of RG58 will do.

An accurate SWR meter can be used to roughly assess the loss, measure
the loss into a shorted line at the frequency of interest, and convert
the measurement(s) into return loss. The matched line loss is half the
observed return loss. The SWR looking into a 65m shorted stub of 9913
at 3.6MHz should be around 19:1, rho about 0.90, for a return loss of
~0.92dB, and a MLL of 0.46dB. (If your SWR meter does not read 100%
reflected on a s/c applied to the SWR meter terminals, don't waste
your time doing the test.)

I agree with Owen, something here doesn't compute. The only way I can make sense out of it is if your line length is really an odd number of quarter waves, and it's exceptionally lossy. As a first thing to do in resolving the matter, I recommend measuring the velocity factor of the main coax. For best accuracy, short circuit the far end of the line with a low-inductance short circuit, and look for a low Z at the input. (You can even use a scope or diode detector for this.) At low frequencies, a single wire will do for the short; at higher frequencies, use multiple wires radially extending from the center to the shield, or a metal plate. At very low frequencies, the impedance will be low, increasining with frequency. At some point it'll rise and become very high, then drop again as frequency increases. Find the frequency where it's the lowest -- this is the frequency where the line is exactly a half wavelength. Physically measure the line and calculate the velocity factor. For line constructed like you describe, the velocity factor should be around 84%. A significantly lower factor probably means it has water in it. If it comes out about right, let us know and we'll go from there.

Roy Lewallen, W7EL

Hi ED,

An old-ages HF multi-band antenna called Maria Maluca was made of two elements (7.65 m / 5.05 m / boom length = 1.72 m) feeded by a twin lead. It is a compromise between size en performances.

That antenna was used by south-american stations (that's where the name comes from). Of course, operation was better in hupper HF bands (some says that 80 m operation was possible!!!).

If someone is interested I can scan the description I have (in a french ... but I can translate it)

Best regards

Yes, it's 50-ohm coax. Somewhere the program tells you that.

Two 1/4-wave resonant coil-loaded verticals, back to back, make one
1/2-wave resonant coil-loaded dipole.

But the dipole is more efficient. There is no ground loss resistance.

Reg.

If you mean gain over a _ 1/2-wave _ dipole, then all of the single verticals > 90 degrees in the plots I posted earlier (with their "image" components) already have greater peak gain than that.

The peak, intrinsic gain of the 90 degree vertical and its image in my plots exactly matches the free-space peak gain of a self-resonant, 1/2-wave dipole (2.15 dBi).

The fact that all of the radiation from these verticals is confined to a 1/2 hemisphere adds 3 dB h-plane gain to all of the plots.

Nonsense.

Properly crimped, the wire will break before the crimp "works loose".

Your tire has multiple lug nuts to spread the stress, not because a
smaller number will "work loose".

5190. Interaction between dipole and beam

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-27 15:43:43 UTC
From: Bill Ogden <wogden@attglobal.net>
Message-ID: <%4dsf.6899$L75.2525@fe12.lga>
Source record: 65985

The QST article about the HyGain 40/30 meter rotatable dipole has my interest. (It discussed using relays to change the dipole between 40 and 30 meters.)

My "small gun" station has a 3-el SteppIR on a 55-foor crankup/crankover tower. The mast extends about 5 feet above the top of the tower. If I add the rotatable dipole on the tower, should it be below or above the beam? Will the spacing (about 4 feet) be so close that I degrade the beam? Would a slightly longer mast be a major improvement? (I already have a dipole and half-sloper wires connected near the top of the tower, sloping to about 10' at the ends.)

With all the publications about ham antennas, it seems there is little reference material about antenna interactions. I realize that each situation is unique and it is a complex subject. Nevertheless, there seems to be very little published in this area.

If you are still thinking of the broadcast television signal, the audio portion is not a subcarrier -- it is a discrete carrier whose modulation can be detected by any receiver capable of FM demodulation, and able to tune to its r-f center frequency.

> proposition with sheer volume.

Not at all. My logic is that they will keep pouring money into it until it makes a profit or they give up. Like UPS did with a portion of the 220 MHz band in the U.S. they lobbied for it, convinced everyone it would be in the public good to give it to them and they took it from the hams.

By the time they got it, it was too late, technology passed them by and they never used it. But it was never given back.

As for making a profit, there are lots of ways to recover cost. Maybe you will start seeing "ads by google" in the middle of web pages that did not have them, or a page request will give you an AOL page first before the page you requested.

Haven't you heard? Google just gave AOL $1bn for the privledge of being bought out by them. From now on a Google search will show AOL pages first.

> The thing is that BPL doesn't scale up all that well. The power line

> wavelength and keep going.

Sort of. BPL uses carrier frequencies like every other digital communications method. If they run out of bandwidth in unocuppied carriers (which don't exist because every HF frequency is in use somewhere), they add more carriers.

If there was a burden upon them to make sure it is not in use, but all they have to do to check that is to listen with a cheap shortwave portable. It's not their fault there is no propigation at that moment or all the hams are asleep. They "checked" and you would have to fight them to get them off it.

> BPL will slow down quickly as subscribers

So what? Once it's there it's there. Once given it can never be taken away.

> I'm sick and tired of seeing the ARRL humping the FCC's leg over BPL
> and being ignored. It's time to add another weapon to the arsenal. If

> not an approach involving regulating BPL to death thru the state PUCs,
> what do you suggest?

I really can't say. I'm not in the U.S. BPL died a quick death here for two reasons. One it sucked. Two, Israel Electric (a country wide monopoly) has been quietly running fiber alongside of their wires. Currently they use it for the monitoring and control functions that BPL is supposed to provide, but if the Ministry of Communications would let them, they would sell the bandwith for internet.

As for the ARRL if you are a member, complain. Their attitude is as long as you don't foul my bands, I don't care. Make them care. Deluge Sumner and Hare with emails. (one per member please, not a worthless mail bomb).

> I don't believe for a second that a call to not use Google will have
> any effect on BPL. It will take millions of people cooperating to
> make that approach effective and you'll never get that many to
> cooperate. Getting the attention of state PUCs takes far fewer people
> to accomplish.

Yes, but with 600,000 licensed hams in the U.S., if they and their families each emailed Google seperately and boycotted Google search engines, Google maps and "ads by google" they would get the message pretty quick.

The owner of one popular ham site wrote me that he could not give up his "ads by google" as the money paid for the site. I told him that he was making a mistake and I would also boycott his site and his advertisers.

It's up to you. If you don't do anything, there will be no HF bands in 5-10 years. Morse code tests or not, you simply won't be able to hear anyhting except buzz-buzz-buzz. :-(

The confusing part, at least for me, was that the entire passband *can
be* downconverted and then demodulated assuming 4.5 MHz separation. That
doesn't imply a *necessary* condition for demodulation.

The model for a simple vertical above ground is simple enough.

Perhaps YOUR way is incorrect if the pattern disagrees so strongly
with EZNEC.

TV audio is not a sub-carrier. The audio is an independent transmitter from the aural transmitter.

They may have come up with some other way since I worked at WXEL in the fifties, but as a fifty's TV set still works today, I suspect the result is the same.

Dan,

If you want to design a shortened dipole with loading coils you should download the freeware package HamCalc. It is a large collection of BASIC programs which run in a DOS window. The package can be downloaded from http://www.cq-amateur-radio.com/HamCalcem.html

There are several programs that deal with shortened, centre and off-centre dipoles. Loading coil design using standard forms such as PVC pipe is included.

Yes, and six drive pegs
http://www.f1-country.com/f1-engineer/tyres/wheelrim.html

so the nut only holds the wheel to the hub and doesn't take the stresses
of propelling the car.

ED-

Back in the 80s a popular small antenna was the "Mini Beam". A friend had one and was happy with the way it worked. However, it was quite fragile, and the small rods in the capacity hats would frequently break.

I did a Google search for minibeam and found several different products currently for sale. I also came across a do-it-yourself mini beam at http://www.telusplanet.net/public/ve6vk/minibeam/minibeam.html. It is a single-band antenna using mobile whips, but may give you some ideas.

Reg,

My models agree with theory and measured results, as have been developed and well-proven for 60+ years in the broadcast industry.

If you doubt my plots, why not send them to Roy Lewallen ask for his comments? You might also ask him to tell you how to model these configurations properly using EZNEC.

I'd explain it, but probably that wouldn't be acceptable to you (plus you didn't ask me).

C'mon Reg, it's only been three months since you last asked this and got it answered(1). The time before that was four years earlier(2), and before that multiple times going back at least to 1998(3). At the rate you're going, you'll be asking it weekly before long. Getting tired of promoting "TLI"s, grumping at "Gurus" (while carefully excluding yourself, of course), grousing about Americans, and asking "Who's Kraus"? C'mon, be original. Surely you can think of a new topic to keep you awake on those long, boring evenings. I've got an idea -- maybe you can use your knowledge to actually help some of the folks who ask serious questions on this newsgroup.

For anyone who wants an answer to Reg's perennial question, use groups.google.com to look up the following threads on this newsgroup, where Reg has asked the same question and where it's been answered:

(1) "best HF antenna system next to a trailer?", Sept. 2005
(2) "40M Delta Loop Advice Needed:", May 2001
(3) "Raised V's burried ground systems." [sic], Feb. 2000
"Ground Radial system comparisons", April 1999
"Is there", Aug. 1998
"Better for DXing: Beam or vertical?", Aug. 1998

You've described how it's commonly generated. But is the end result any different than if it were generated instead by modulation of the main carrier by an ideal modulation system not having the practical problem of intermodulation distortion? That is, isn't the end result identical to a subcarrier?

When I worked in radio broadcasting in the '60s, we generated an FM (SCA) subcarrier in addition to the stereo subcarrier by modulating the transmitter. Some stations had multiple SCA subcarriers.

Though people often concern themselves about whether UHF connectors
introduce significant impedance mismatch / loss, to my mind the much
greater problem is their reliability.

The 'outer' connection depends on being properly seated and coupling
ring tightened very tight for reliable connection. The connectors work
loose readily and are then unreliable at any frequency.

UHF connectors are an example of a poor design that will probably
never be displaced from the amateur market.

No, in that an aural subcarrier would disappear without a visual carrier to convey it. TV aural via a standalone r-f transmission system would not.

Sorry, I obviously failed to communicate my question. Let me try again.

With no information other than looking at the composite signal including video and audio, would you be able to tell if it was generated by two separate transmitters or by modulation of a single transmitter by the video and an audio subcarrier? That is, if you could do the modulation without generation of intermodulation products.

From: Gary Schafer <gaschafer@comcast.net>
Message-ID: <6bo3r1d3cpu9a81illbs9np90n4sldib3j@4ax.com>
Source record: 66011

It is not a sub carrier in the rf spectrum, meaning it can be fully
seen with or without any other carrier (video), but when detected in
the TV receiver it becomes a sub carrier of 4.5 mhz in the TV's IF.
The audio carrier is mixed with the video carrier to produce the 4.5
mhz.
Without the video carrier the TV receiver will not see the 4.5 mhz.

As others have said the sound carrier is usually generated by a
separate transmitter at the sound carrier frequency. But it could also
be generated as a sub carrier of the main video carrier with the same
results. It would still be visible in the RF spectrum just the same as
it is when generated by a separate transmitter. The main carrier would
also have to be present at the same time of course.

However if the TV video signal was an FM modulated signal rather than
AM then the sound sub carrier would not be visible without the main
video carrier if it was generated as a sub carrier.

The same happens with an FM broadcast SCA sub carrier or the stereo
sub carrier on the main signal. The main signal must first be
demodulated in order to demodulate any sub carrier.

The r-f spectra of TV aural signals and FM SCAs are standalone entities. Each may be fully demodulated by a suitable FM receiver capable of tuning to that r-f spectrum. No "main" carrier is needed. Given, this isn't the conventional practice -- however it would be possible to do.

Likewise, the L-R audio information of an FM stereo transmission is a standalone entity, and given a suitable r-f receiver and detector, it can be fully demodulated back to L-R without needing the main carrier. Not conventional or cost-effective, but possible. Of course, the L+R waveform conveyed by the main carrier is necessary to matrix with L-R to produce the L&R channels needed for stereo reproduction by the receiver system.

You really want the lower of the two higher than 20ft.

It's really simple, higher is better. We are talking VHF and if there
is nothing going on propagation wise then height above average terrain
determines what your radio horizon will be. For that higher wins.

Simply put, 80ft will be much better than 20 and only slightly better
than 40.

~~~~~~

I'm not that sure about loops, but for yagis working DX, the optimum
height seems to be about 35 feet. Higher is better for ground wave,
but for DX, 35 is best, believe it or not. This has been proven with
crank up towers many times. It may well be the same for loops.

The program coaxpair does not seem to compute the reflection angle. Is this an error? Is the cause known?

Thanks - Dan

==========

Dan, I don't know what you mean by "reflection angle".

The program DOES compute the angle of the reflection coefficient. The
answer is in the bottom left-hand corner of the screen.

When the terminating impedance, Rt+jXt, equals line impedance, Ro+jXo,
the magnitude of the reflection coefficient is zero.

But zero magnitude cannot have an angle. Its a mathematical
impossibility.

But when RC = zero the program is obliged to print something for the
angle, so it prints an indeterminate angle which can lie randomly
anywhere between +180 and -180 degrees.

Actually, you can't set the RC exactly to zero because the program
only works to 14 decimal places.

The randomly generated angle can't be used for anything because when
the RC is zero there's nowhere in an equation to insert it. Just
forget about it. It's meaningless.

And even for a very small magnitude of RC the value of the angle
doesn't matter very much. It has little effect on what is being
calculated.

I can answer for him. Stacked loops offer some amount of gain
but are omnidirectional. A 2 element quad, offers slightly more gain
but is directional. If both are on the SIDE of a tower, one has to
be turned and is expensive to do that.

Actually a single loop has better high angle when mounted high up
than a stacked pair.

After trying a lot of 6m antennas. Quads with wires thinner than 1/4"
are only ok but doo poorly with ice and high wind. I'd do a yagi of
4 or more elements for gain and F/B and a loop up high for local
nets(omni).

> distances. I assume that in the UK, it is calibrated in metres.
> Do you guys call that device a "metre meter"?

Cecil, We'd call it a
1) Metre measuring device, indicating
a measurement solely in Metre Units
2) distance measurement meter. In
English terms your pronunciation of Metre Meter would
also be grammarmatically incorrect and not good
English, in speaking terms.

Much the same as 1) Tonne, a metric measurement of weight. IE,
a mass equal to 2,205 Lbs.
2) Ton, a unit of weight. IE,
an English Imperial unit equating to 2000Lbs. Also
3) Ton, a unit of weight. IE,
A weight of 2,240 Lbs, equal to 1.016 metric tons, known
as a long Ton.
And you though you were confused Eh!!!!! 73's De Dave LOVL

Hi Charlie

I have read some of the responses you have received already. As you asked for first hand experience I hadnt commented initially.

I wonder if you have tried modelling your configuration with height variables and applying the resultant radiation pattern to propagation modes? I'd suggest ground conditions for your area also need to be entered. I seem to remember from my dim dark past that ground reflections (and hence undesirable skyward radiation - often not usually an issue on VHF) are more of a problem when using a lower gain antenna. Maybe the loop in that respect might be worse than a quad/yagi?

You'd be able to see the dB per foot height changes that occur and make a judgement from that.

I have never used horiz loops on 6m.

Cheers Bob W5/VK2YQA East Texas

Reg,

I am dealing only with the open circuit case and trying to determine the reflection angle of the reflected signal at the source. In those cases the angle was always zero.

However the angle calculated is the reflected angle at the termination. In the open circuit case that is zero.

After making an error here between the effects of odd versus even quarter waves at the source I am getting closer to being able to measure the impedance of a loaded vertical 'in the shack'. At the moment this is limited to a single frequency 'close' to a frequency of interest. But even that is a triumph.

Thanks for the reply. Dan

Polyphasor stands out as a company that tests and evaluates their products with EMP lab testing and actual lightning strikes, not sure about the other brands. Iï¿½ve visited many commercial mountain top repeater sites and Polyphasor is the only brand that seems to be used. The only complaint I've heard is the VSWR may not be as advertised in the VHF and higher range. Unless you need to power something via the coax, use a DC blocked unit. I donï¿½t think a DC pass arrestor can roll off energy in the HF range to adequately protect your radio. The arrestor needs to be placed at the cable entry point to your house/shack and well grounded to do its job. You might want to read Polyphasorï¿½s book that will help you design a system that will have a chance of surviving a lightning strike. A poorly design system is probably worse than no arrestor due to the false sense of security it may give you.
I have absolutely no connection with Polyphasor, bla, bla bla.

If you are trying to make real-world measurements, a true
short-circuit (~zero) is actually easier to implement than
a true open-circuit (~infinity)

5242. SWL Antenna Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-28 17:42:45 UTC
From: Ben Sinclair <bensinc@gmail.com>
Message-ID: <1135791765.713949.172040@o13g2000cwo.googlegroups.com>
Source record: 65938

I have a new Icom R-75 and have some newbie antenna questions. I have a random length wire in the length my attic, and the receiver is located in the basement.

The R-75 has a two antenna inputs. One coax, and one for a wire with a ground input. I attached my random wire to the wire antenna input and it seems to work, but there is a high level of noise on everything, even WWV stations. Connecting the ground to my house's ground doesn't make any difference.

I'd think the problem is that I have an antenna that has to snake around the house, near electrical wires, computers, lights, etc. that are causing interference.

I think a solution is to connect the random wire to shielded coax and run that from the attic to the basement and hopefully that will reduce interference. I think I need to use an impedance matcher to connect the wire to the coax, like this one:
http://www.shortwavestore.com/sws/product.php?productid=465&cat=0&page=1

Does this all sound right, or is there a better way to do this? With the random wire connected directly to the receiver, I can pick up a lot, but it's very noisy.

Thanks!

5243. Tri-ex vs US Towers

Hi- I have a used Tri-ex W51 that I picked up in an auction. I need to get a base section to set in concrete. I have heard that US Towers makes a suitable base or Tash Towers also has one. Are there any advantages or disadvantages of going to either manufacurer? Thanks in advance. Steve K9SL

Hi Ben,

Sounds like the right answer, short of putting your antenna outside
(with the same shielded coax).

>I think I need to use an impedance matcher to connect the
>wire to the coax, like this one:
>http://www.shortwavestore.com/sws/product.php?productid=465&cat=0&page=1

Will do nothing for noise that you haven't already accomplished with
the coax. Further, it says nothing of what's inside, nor offers any
specifications - just marketing snake-oil.

You could also choose to "choke" the end of the coax by using ferrites
in any of several forms. Research W2DU style BalUns on google and pay
attention to the theory of their operation.

Also, obtaining a very cheap ham 3 knob antenna tuner (without meters)
will perform all the matching you could wish for AND it will eliminate
the most common form of desensing for SWL (front end overload from out
of band transmitters - your friendly neighborhood AM station being
most often the culprit).

Steve -

My personnel preference would be to go with Tashjian.

Tashjian currently produces towers under the TriEx name and they acquired
the TriEx engineering drawings.

After a number of well publicized cellular tower accidents (e.g. collapse,
accidents) many municipalities and county government placed new laws for
building permits and insurance coverage.
This is one reasons that you see the service being offered by Karl K.
Tashjian for commercial usage of these towers.
http://www.tashtowers.com/engineering.html

You should request the engineering specifications from Tashjian on your W51
tower.
http://www.tashtowers.com/wt51.htm

Lastly, your tower becomes part of your overall property - which is one
reason that building and property inspectors are now largely involved.

Hey all,

I'm still skeptical about this formula:

Field Strength (uV/m) = 10 ^ ((107 - |dBm|) / 20)

Is this valid? I saw this formula somewhere and jotted it down.

Thanks!

dBm is a measure of power, and the field strength as a function of power is going to depend on antenna characteristics.

The equation you have is a pretty direct conversion between power in dBm to voltage, with a magic proportionality factor (the 107) buried in the exponent.

So I suspect it's a valid function, but only for one type of antenna.

Thanks for your response. I live out in the country and own the property all around the tower site with the closest neighbors appoximately 1/2 mile away so I am not worried about the tower falling on somebody but I am concerned about the overall robustness of the mount. I looked at the different webites and it looked like us towers had a larger footprint for the concrete pad than was speched out at tashtowers. I just wonder if it is way overkill for my application since the are building these bases for their own (ustowers) design. Any thoughts?

It is if the propagation isn't there or the moon is not a good shot.
;)

Then again I only have 14 countries on under 20W in the last 3 years.
I need KH and Alaska for WAS. RI is next door for me being in MA.
Even with the off peak years there is a lot of propagation
that pops up at odd times.

Real simple. He's so close to the ground he has a lot of high angle
gain. As he goes up that will go down and the low angle gain will
improve.

>I have never used horiz loops on 6m.

Handy for local stuff like a 100 ore more miles in all directions.
I use one for the listening as I miss stuff with beams.

Source record: 65948

There's not enough information to calculate field strength. There's a direct relationship between uV/m (field strength) and W/m^2 (power density), providing you're in the far field and you know the intrinsic impedance of the medium (about 377 ohms for free space). But you need a distance from the source and the antenna gain in order to know what the power density is for a given power (dBm). So at the very least, you have to specify the distance from the source and the antenna gain to calculate field strength from dBm. And then it's valid only in the far field.

Each tower engineering design and recommendation is based upon a set of assumptions about soils, drainage, tower stresses and wind loads.

The "size of the concrete footprint" is the engineer's design based upon these assumptions ... I would not venture into guessing what these criteria were --
I would ASK each vendor.
I think you will find that their assumptions are different and all you are seeing is the physical changes required based upon those assumptions..

Also, I would ask US Tower, before purchase, about using their base on your TriEx Tower .... you are "mixing" designs.

I would desire to get a "sign-off' by their engineer for such a substitution.

I understand your rural, no neighbors situation - BUT it can fall on your house.
Towers are of little resale value without the supporting engineering paperwork.

First off, what do you mean by LOOP? A Halo kind of antenna, or a vertically mounted loop? I suspect you mean a Halo (or M2). I ran an EZNEC simulation on a stacked pair, and it was not great. Minimum stacking distance is a bout 13 feet, with a gain 2db less than a single 3 element beam. Get the bugger up to 80 feet. A friend of mine had bought 2 M2 loops. Never bothered to put up the second one when he realized that you can't just stack them 3 feet apart.

Remember, 20 feet is already a wavelength up. If you really want high angle radiation, it would have to be a lot lower than that. That will work for E skip, not very good for F2, or locals. Even at 80 feet, you will still have multiple lobes, with a good part of the energy going almost straight up.

dBm significant the logarithm relation to Power (mW). In case of field strength or voltage (mV) you have to multiplication with 20.

Take a look at:

http://www.sengpielaudio.com/calculator-volt.htm
http://www.nobbi.com/conversion.htm

and very good:

http://en.wikipedia.org/wiki/Decibel

Your expression does not apply in general, it is the unstated
assumptions that are the issue (freq, receiver R, antenna factor.
bandwidth).

The calculator at http://www.vk1od.net/sc/FS2RPCalc.htm my be of
interest.

With an Antenna Factor of 0dB/m (eg 0dBi gain at 30.83... MHz), a rx power of 0dBm/Hz in a matched receiver, would be the result of a field strength of ~107dBuV/m/Hz. So, the lhs of your formulat is in units of dBuV/m, and assumes AF=0dB/m and 1Hz bandwidth. AF depends on antenna gain and frequency, and antenna / receiver R.

I do understand the problems some folks have with needing to satisfy
the political establishment.

However, when I refurbished my crank up free standing mast (about 55
feet) I took the position that as near as I can tell in my rural world
if it don't spill over onto some else's property, I can do want ever I
am willing to risk.

When I was specifying the concrete I discovered that whatever I
ordered, the concrete company was going to charge me for a minimum of
5 yards. 3-4 would have done the job...

The hole was not a problem, I have a back hoe. The steel was not a
problem either, just make sure there is 50% more than anyone thinks
you need, they sell it by the pound!

The supporting gantry was designed the same way. If a 6" cross section
will do, go with 12", when you are buying from salvage yards you only
have to find enough material to do it one time!

Build it so it cannot fall down!

OOPS! - sorry, I forgot about 50M DX - skip does happen at 50mhz sometimes
I hear its an enjoyable pass-time to attempt long-distance short-duration
contacts on 50mhz.
Does ducting also occur on 50 ?

Is that as hard as it looks?

Take an example:

You have an impedance meter to measure complex impedance at the
frequency of interest, being 3.6MHz for the sake of the example.

(This technique depends on the behaviour of the tranmission lines, you
would want to be sure that the transmission lines are in good
condition and work as characterised.)

You measure the impedance 40-j15 for example looking into a cascade of
5m of RG58 and 50m of 9913 connected to the unknown load.

The Z at the load end of the RG58 is 60.42-j20.13. That is the Z
looking into the 9913.

The Z at the load end of the 9913 is 41.94+j18.03.

Is this the kind of thing you are trying to do?

Bear in mind that you cannot know the characteristics of the lines etc
to support the precision shown above. You also need to keep in mind
the sensitivity of the results to changes in parameters to form a view
of the confidence limits of your measurements.

This took more time to write about than it did to find the results.

Propagation to Japan, Australia, Greenland, Chile... ain't skip.
It's F2 -- or Es-connected F2. Gets Real Crazy every 11 years or so.

> Does ducting also occur on 50 ?

There's little that doesn't occur on 50 MHz. I have completed QSO's by
Es, F2, Au, meteor, tropo ducting, and weird flavors and combinations
of more than one of'em. Fellers also do EME on 6M - tho' not I.

When the band is wide open on an Es opening -- maybe a 2X Es event --
you'll find the FB-OP-to-Jerk ratio Real High. It's one of the reasons
I've all but given up on the 'popular' HF bands.

And, to steer it back On Topic:
Fiddl'in with antennas on 6M is SO EASY.

5262. Recommendation for 915MHz omni antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-29 02:29:14 UTC
From: David <webreply@orbitcoms.com>
Message-ID: <_RHsf.124838$V7.65294@news-server.bigpond.net.au>
Source record: 65959

Hi,

I am looking for recommendation for a design of antenna to operate
in the band 915-928 MHz.

The desired response is omni-directional with gain greater than or equal
to a 1/2 wave dipole, something that does not require a ground plane
and is reasonably straight forward to manufacture in-house.

So far I am considering a 1/2 wave vertical dipole with feed through
lower element, J-Pole and Collinear.

Thanks in advance for any ideas or link to a web site that might have
some homebrew versions I could replicate and try.

--

Kind Regards

David Huisman

A guy named Salvati has several articles in EDN etc on using
active antennas. Add his name in the google search.
IIRC, he used J310 JFETs to add the active portion of the
circuit.

Good luck,
Dave

5264. Re: coaxpair reflection coeff angle is 'zero'

Owen,

Thanks for the example. I do not have an impedance meter. I do have a vector voltmeter that will read the phase and value of the reflected signal.

The core problem is: How to measure and improve the performance of a loaded vertical. The unknowns are the value of ground and antenna resonance.

Setting the coax to a 1/4 wave multiple was a way to remove its phase altering characteristics from the reflected signal at a frequency of interest. That seems to be working and is predictable to measure the 1/4 wave odd, open circuit, resonant points, etc. This simply proves consistent measurement and correct identification of the electrical cable length.

I am pretty confident about the coax measurements at this time. Now on the to antenna. I am not what the reflected angle is from the antenna. The coaxpair program predicts it can vary 180 degrees for a purely resistive load.

Thanks for your help - Dan

If you mean relative to the forward wave, then you can calculate Z
from that.

I don't know that that is necessary or helpful.

>

Yes, the complex reflection coefficients for a 51+j0 ohm load and
49+j0 ohm load are both very small magnitude, and 180 deg different in
phase.

Don't worry about the reflection coefficient at the antenna, find what
it is at the instrument interface, calculate the Z, and use one of the
many calculators to work out what it is at the end of the line (they
use the input reflection coefficient and propagation constant to do
that, but they do it internally).

You know that Gamma=(Zl-Zo)/(Zl+Zo), rearrange the terms to find Zl
knowing Zo and Gamma, measure Gamma with your instrument, calculate
Zl... and the rest is easy.

Back to my worked example, if you instrument indicated Gamma was 0.195
< -117 in 50ohms, you would calculate Z to be 40-j15... and go from
there.

What more do you need?

Richard, I thank you for your time and trouble expended in trying to educate me regarding the field strength from a 1 Kw transmitter at a distance of 1 Km.

Your efforts, of course, will not be wasted on other readers of this newsgroup. Very good stuff!

But you have misunderstood my attitude towards this discussion.

As I have said before, amateurs and professionals alike, all suffer from delusions of accuracy. The uncertainty in prediction of field strength of groundwaves can amount to 10 or 15 dB or even more at extreme distances.

When I say my program correctly predicts a field strength of 300 millivolts per metre at a distance of 1 Km from a 1 Kw transmitter, nobody can disprove it. Even the 'bibles' state it as a matter of fact. But we all know how much faith can be placed in 'bibles'.

To be of use, all measurements should be associated with an uncertainty. Only then can the originators be judged to understand what they are waffling about.

Thank you for your interest.

Reg, G4FGQ.

For avoidance of doubt, the Zl above is the z at the instrument
interface. 'The rest is easy' is the process of working out Z at the
antenna knowning z at the source end of a known transmission line.

>Back to my worked example, if you instrument indicated Gamma was 0.195
>< -117 in 50ohms, you would calculate Z to be 40-j15... and go from

You're making this way too complex (pun intended).. Why not just
connect the coax to the bridge and put your open-short-load standards
on the far end and do the calibration?

Or move the instrument out in the field?

For example:

Ben: Welcome to the world of SWL'ing in the new Century...

It sometimes seems the whole world is a huge RF noise generator, and the more urban your listening location, the worse off you're likely to be. Too, just wait 'till 'BPL' (broadband over power lines) becomes a reality...

Known RF noise generators commonly found in the home:

Light Dimmers
Computers
Televisions
Fish Tank Heaters
Electric Blankets
Microwave Ovens
Cell phones

And if you're in a suburban neighborhood, these noise sources can be coming from any (or all) of your neighbors homes.

If you're attempting to hear the microwatt station from Micronesia, you'll need a well considered antenna system to improve the signal (good) - to - noise (bad) ratio.

Generally this means an antenna that is erected as high as possible, and at right angles to known noise sources.

An antenna tuner attempts to 'transform' the impedance of a random length wire to 50 ohms; useful in *transmitting* applications, but of little or no use in reducing electrical noise interference to a receiver.

A better bet would be a device that captures the same noise as your main receive antenna, then 'compares' this common noise signal and cancels it out. Search for the 'Timewave ANC-4 RF Filter', a somewhat fussy, but very effective "locally generated noise eliminator".

Good Luck.

Wes, I have been guessing that Dan wants to measure the antenna over a band of frequencies, and doesn't want to be popping up to the feedpoint for every frequency cal.

No doubt, the process you propose Wes is simpler and more accurate, if it is physically convenient.

Would calibration against a single s/c standard be accurate enough for the purpose at hand. Perhaps a coax relay at the antenna feedpoint to switch between a s/c port and the real load might be accurate enough for calibration, and a whole lot more convenient. IIRC there is only around 0.4dB of line loss from the shack (ie the desired VVM location) to the feedpoint.

Dan, I think you have gotten on a sidetrack about building the transmission line out to a tuned length. It is not necessary, or even desirable as far as I can see, but it has the downside of complicating the calcs and increasing scope for errors when you build out with a different line type.

Interesting point of view, Reg.

The correct application of physical laws disproves your contention, and the equations that do it are not difficult. Here they are:

E = SQRT(49.2*P)/D

where E = Peak inverse (free-space) field from a self-resonant, 1/2-wave dipole (volts/meter)
D = Distance (meters)

As radiation from a vertical antenna with its base at ground level is confined to one hemisphere, field strength at that distance over a perfect, infinite, flat "ground" plane is E * SQRT(2).

This generates the value of the maximum possible field from a perfect 1/4-wave vertical radiator over a perfect ground plane, which has been proven and used for many decades in the broadcast industry. This is the groundwave field that then is subject to various propagation losses related to earth conductivity, diffraction etc over long paths, once the radiation has been launched. N.B. -- at a distance of 1 km, such losses are negligible for the typical broadcast vertical with its 120 buried radials, regardless of ground conductivity.

Why not use the formulae in your program that actually generates the correct value, instead of just saying it does, or implying that your approach is "good enough?"

Source record: 65876

And to complicate matters further the max antenna height being talked about being around 3-4 wavelengths off the ground is going to break the radiation pattern up into a number of lobes at various vertical angles.

For that reason alone I think it is still worth modelling. There will be specific heights where the horizontal radiated component is at a maximum and this is likely the most desirable. It will also give a good indication of what takeoff angles will be like for ionospheric propagation modes. You'd also see the spacing/height effect on undesirable straight upwards radiation.

Then again a crank up/down tower and maybe inter element spacing adjustment mght be a good empirical way to get the right data as well.

As someone who is contemplating retirement from formal teaching duties after
42 years of teaching EE, Reg provides me an important bit of instruction
about retirement. All of my life, I have noted those I wish to emulate and
those who I wish not to emulate.
More experienced people (read: old folk) are able to contribute stories
of things to do and not to do. Reg and several others here have done just
that. Many important or practical parts of the art are not easy to find
even with the WEB. Knowledge should be cumulative.
On the other hand, tossing a stick of dynamite into the lake to see how
many fish come to the surface (this time) is in a different category.
73, Mac N8TT
P.S. Obviously, if the question were posed in law school, the best answer
would be to show that the "If" is not satisfied. Since the ideal length of
an antenna is not 0.25 WL, the remainder of the issue is moot.

David

You are going to have to be more specific as to your intended use.

Assuming you are talking about being omnidirectional horizontally from the antenna, virtually any form of collinear construction would suit. This is provided the gain doesnt get so high and the vertical half power beamwidth doesnt get so narrow that your use of it drops out of the pattern. (These gain and beamwidth figures being inversely related)

For ease of manufacture I'd probably go for a centrally fed collinear array with a number of 1/4 wave phasing sections. I'd feed it at the centre phasing section in a similar manner to a jpole but with a 4:1 coaxial balun. You could make this antenna from (say) a single 3/16" copper pipe/wire length. This construction may not suit if you want to run it indoors but will be well suited to side tower mounting.

A "super" jpole or one with a phasing section and extra half wave on top might be another option. Part the way through this page;

http://www.cebik.com/vhf/jp4.html

Something I havent proven to myself so please take this with a grain of salt, when feeding a vertical collinear antenna from its base very good feedline decoupling is needed to reduce the effect of skying the pattern from the antenna . What is more of a problem though (and what I havent researched) is that without allowing for power loss (through phasing delays etc) from one element to the next means you have the same radiation skying effect, the lower elements radiating more than the upper. One trick here is to mount then antenna inverted or complicate the construction with a centered feedpoint.

I havent checked websites for 900MHz plans but I have heard that they are very popular. It may even be cheaper for you to purchase two medium gain commercial products (that required a groundplane) and arrange them like a dipole, feeding them through a 1/4 wave Q section. If an antenna is designed to be 50 ohms resistive over a ground it will be close to 100 ohms in dipole mode. (Making the Q section 75 ohms will do the trick)

Hope this is helpful

Cheers Bob VK2YQA

Source record: 65974

I am not looking to punch any holes in the walls or ceiling to get a coax from an outdoor 144/440 Mhz antenna. I'm setting up a mobile rig powered off an Astron Power Supply in order to allow my wife to communicate on some of the local repeaters so she can talk to and follow me into work.

The antenna can be simple as something that has a magnetic mount that sets on top of the power supply or something that might present some measure of gain. If any of you have eny experience with either building antennas or have one you purchased that you really like I would love to know what it is and consider it to fit my needs.

Thanks in advance

Gary

Thanks for the replies! Yesterday I connected my random wire to the center of my coax and strung it down to the basement. It seems to work, but there is still some noise. I don't really have anything to compare it to though.

I'll research the noise filters and see what I can find. Is the W2DU balun something I should still consider? The "wire man" has several and they are fairly inexpensive, so I could at least try one.

I don't know a lot about how propagation works, but does it seem normal that In the early evening I could hear WWV on 10, but not 2.5, 5, or any other frequency, then late at night I couldn't even hear it on 10? This morning it was again coming in loud and clear on 10, but not any other frequency.

Wes, and Owen, This problem of how to resolve the terminating impedance
seems so simple that I realize that I (again) must be missing something.
Wouldnt it be accurate enough for Dan to record the impedance at his coupler
for two conditions, 1) short circuit at the antenna end of the coax, and 2)
the antenna connected. Plot both impedances on a Smith Chart. Since the
impedance associated with the short is known to be zero, he needs only to
rotate *both* impedances thru the same angle needed to place the short ckt
impedance at zero on the smith Chart.

Hi Gary

How about a extended double ZEPP made from aluminium foil stuck to the window.

I saw a design somewhere that was 5/8 over 5/8 on 70cm and kind of like a dipole on 2M. The hairpin section was kind of long (more than a 1/4 wave) It wasnt a foil on window variety but the design would still work.

It was on one of the VK PBBS's some time ago. If you cant find it on the web get back to me and I'll have a look.

Yes it is a dual band antenna 144/440.

Cheers Bob W5/VK2YQA

>From the NIST WWV FAQ:

"Multiple frequencies are used because shortwave propagation varies with many factors, including time of year, time of day, geographical location, solar and geomagnetic activity, weather conditions, and antenna type and configuration. In general, the lower frequencies of 2.5 and 5 MHz are best during nighttime hours, the higher frequencies of 15 and 20 MHz are better during daytime hours, and 5 and 10 MHz are probably the best compromises overall. The 5, 10, and 15 MHz transmissions are at higher power than the other frequencies."

wrote:
>I'll research the noise filters and see what I can find.

Hi Ben,

They are nice toys suitable to sources of noise that are not easy to
fix, like a power pole arcing (or a neighbor's electric fence around
the horse pasture). Still, if you simply visit the neighbor and offer
to fix his problem (grass is too high, or a wire is drooping); or call
the utility (it is in their interest to fix their noisy poles); then
you've not only saved money, you don't have that noise anymore.

>Is the W2DU balun something I should still consider?

Like I said, research the theory behind it. You don't actually have
to buy anything if you coiled the far end of the coax - research the
properties of a transmission choke. Choking your transmission line
can push your home's contribution of noise down considerably.

>I don't know a lot about how propagation works, but does it seem normal

This is one of the hallmarks of listening to WWV, WWVH, or CHU or any
number of time stations or beacons (CHU, located 15 km southwest of
Ottawa, transmits on 3330 kHz, 7335 kHz, and 14670 kHz). They give
you an indication of how well propagation is working from those
points, to you, on those bands at any particular time of day (which is
a significant factor). They are always there, and always at a known
power level. For example, this makes it quite simple to determine
that if you cannot hear WWV at 2.5MHz with 1KW, you are not going to
hear anyone else in Colorado on 2.5MHz unless they have substantially
more power. On the other hand, there is nothing in that region to
listen to anyway given this is an extinct marine band, and the seas
around Fort Collins evaporated millions of years ago.

Modeling will show that at great distances from the antenna, the horizontally radiated field is zero from any horizontally polarized antenna over ground.

This is off-topic, but I thought the old timers in this group might know about this.

I am involved in some scientific work and we have been trying to find information on a device that was around in the 1950s. It's called a Tenescope and it measured the number of lines (in two directions) in the Earth's magnetic field.

Is anyone familiar with this device? Thanks.

I've had good success in the past with a mag mount on a pizza tin, set
on the highest cabinet that I could find. I've been considering a 1/4
wave ground plane hanging from a hook in the ceiling with a piece of
twine or some more attractive insulator to isolate it from the hook.

I've provided a spreadsheet that facilitates the calculations over a
range of frequencies.

www.qsl.net/n7ws/8405.zip

So a couple of trips to the end of the cable are all that are required
to calibrate the setup.

(I must confess, I haven't tried this program with a line much over a
few inches in length to determine whether my calibration functions can
handle it, but I think so.)

Without doubt, the chance of errors creeping in using a long cable is
increased, but the alternative of trying to "calibrate" a cable and
subtract its effects mathematically is equally suspect. In fact, the
one-step process is pretty much the same thing; the cable is being
characterized by the calibration process.

Certainly workable!

Another option is to build some sort of antenna right on one of the
windows, using either thin wire (hookup wire, or even Kynar-coated
wire-wrap wire) or adhesive-backed copper tape (can be found at stores
which sell stained-glass-construction supplies).

One configuration would be a J-pole-like antenna, with a matching stub.

Another would be a vanilla center-fed halfwave dipole.

A third would be a simple "slot" antenna.

Please see http://www.cebik.com/vhf/ex6.html on the topic.

Near the end of the article he gets into the horizonatally polarized
less than 1WL interrupted loops typical of 6m (halos, squares and
triangles).

For more, he also has an article on HOHPLs (horizontally oriented
horizontally polarized loops 1WL and greater).

Worth reading and observing the models used.

Pending some clarification from one of you (or anyone else) as to what is meant here, I point out that h-pol radiation directed toward an elevation at/near ground level has been, and still is the basis for very successful commercial broadcasting by FM and TV stations.

I need to clarify this. It's based on a theoretical model which doesn't apply in many practical cases. It assumes that the signal reaches the destination by two paths, direct and via reflection from the ground; that the ground is perfectly flat at the point of reflection; and the destination is very far from the source. The lower the elevation angle being observed, the farther the destination has to be for this effect to occur. For example, consider the field strength at an elevation angle of one degree from an FM transmitter whose antenna is 1000 feet above the average terrain. Neglecting Earth curvature (which probably shouldn't be neglected in this case), at a very distant point, the reflected signal which will interfere with the direct signal strikes the ground at a point about 11 miles from the transmitter. The receiver would have to be more than 22 miles away (and of course, higher in elevation than the transmitting antenna) for reasonable cancellation to occur. At a half degree elevation angle, the receiver would have to be twice that distance; at a quarter degree, four times, and so forth. Full cancellation at zero elevation angle would occur only at an infinite distance. In many practical situations, you can safely assume that the potentially interfering ground reflection takes place beyond the receiver, so a better estimation of received signal strength can be obtained by looking at the free space pattern.

Hi all:

Here's something I'm having trouble figuring out: My stereo FM receiver has a "fried egg" static that's almost strong enough to drown out the broadcast signal. I've tacked up a Radio Shack 300 ohm yagi in the attic over the garage and the static seems even worse.

Meanwhile the two cars in the garage below get the same signal very clearly. The yagi lead is coax all the way. The broadcast antenna is 15 miles to the west and the yagi is aligned north-south.

We'd appreciate any ideas, and Happy New Year!

Message-ID: <SHZsf.129540$V7.65639@news-server.bigpond.net.au>
Source record: 65895

Bob,

Thanks for the response.

The first is for a poultry house monitoring system that consists of
several "sheds" that may be several km away from the main house.
In addition to coms between the sheds and house, there are links between
sheds (hence require omni directional).

The antenna will be mounted no higher than 3km from the ground and
generally the ground between the antennas is flat.(some installations
may have mild undulations)

If I were to scale up the dimensions of the Super J-Pole shown on the
site, would I need to scale the element diameter too ? This would make
the element diameter less than 1mm at 915 MHz ?

Secondly, is it normal to make the 150MHz version and test it then scale
it up based on optimized dimensions from the lower frequency test ?

Regards

David Huisman

From: Bob Bob <bob3bob3@cox.net>
Message-ID: <2n8e83-f3o.ln1@p400bob.personal.cox.net>
Source record: 65901

Hi David

Okay so you can afford to use a relatively high gain system. You also need to have the antennas high and clear as you can assume that 900MHz is line of sight. You could model the exact environment if you have non LOS paths. That will indicate whether it will work or not. Changes in antenna gain for an omni probably wont help much if the link is marginal when modelled. You could also establish whether you could (say) do the whole system with simple 1/4 wave whips! (A 6dB increase in power or combined antenna gain over an LOS path gives you twice the range)

If you are scaling an antenna yes you need to scale everything. I didnt suggest you scale the Cebik antenna, just wanted to show you the possibilities. It might however be more use to build an adjustable one and have some method of recording/measuring the field strength and changing dimensions for a maximum. I wouldnt call the super J pole an especially critical design for dimensions though. You could for example use 1/8" brazing rod for elements and make the length marginally shorter by the amount indicated in end effect tables. The more elements you have the more critical the dimensions and adjustment will become.

I would say it isnt normal to build at 150 for 900MHz. Too many variables to account for.

What is on 900MHZ? Is this a data network like 2.4GHz 802.11?? Will multipathing be an issue? (High data rates usually need directive antennas not only for a satisfactory S/N with gain, but also to reject any possble multipathing problem of a data bit arriving later than it should.)

Cheers Bob

That's a good idea!

Wes, does it collect enough information to be able to correctly
calculate a phase constant on longer feedline. Some work for the next
version perhaps?

A few comments;

Car FM radios tend to be far more sensitive than "Stereo's" that one sees in the home. They are also better shielded against noise.

I'd suggest your receiver has some major sensitivity issue (like a blown front end from a close lighting strike etc). Its unlikely but there could also be a local interferring source causing a problem. This would be very unusual on FM though. Can you hear other stations well?

As decribed the yagi is aligned at right angles to the station, where minimum signal will be! A check of connections and matching (you said 300 ohms then coax) will also be in order.

Roy, I prefer my radiation patterns to be functions of the antenna itself. After all, that's what it's all about.

To determine the field strength at a distance I prefer not to take any notice of Eznec's misleading ideas on the state of the ionosphere or groundwave loss and do my own calculations. Or I can follow up Eznec by using a program dedicated to either groundwave or ionospheric propagation.

I agree preferences will differ. But it is important to understand exactly what radiation patterns do or do not mean.

Please do not take this note as any criticism of Eznec. It is a valuable (and free) calculating resource. But, as you demonstrate, it is difficult to describe in a few words exactly what it does.

Please simplify!

Reg.

A potential problem is cable loss. When the line Z0 is close to the impedance being measured, loss doesn't have much effect. But if the two impedances are very different, a surprisingly small amount of loss can have a significant effect on the observed input impedance.

Of course, the short circuit measurement will give you the cable loss, which can then be used in the calibration process. It's just that you wouldn't be able to do the correction by the simple equivalent of a Smith chart rotation.

How have you connected the 300 ohm dipole to the (assume) 75 ohm coax?
May I also assume you used a balun to properly make this transition?
Is your area served by more than one FM broadcast station? If so, are
the other stations also affected by the noise?

If so, you have a locally generated noise problem. Do this: Find a
small, portable, battery powered AM radio (like you'd take to the
ball-park to hear the play-by-play (!). Tune it to a very weak AM
radio station. Note: To do this, you may have to be some distance
away from you home, since we've already discovered it has RF noise
polution. As you approach you home, listen for the noise to increase,
while turning the receiver - that's turning with an 'r' - you're using
the receiver as a direction finder - listening for a peak in the noise.

In this way, you likely be able to pinpoint the noise source fairly
quickly.

Likely candidates include:

Light Dimmers
Fish Tank Heaters
Electric Blankets

That's just fine. All antenna modeling programs I know of allow selection of a free space environment, which gives you just what you want.

> To determine the field strength at a distance I prefer not to take any
> notice of Eznec's misleading ideas on the state of the ionosphere

EZNEC makes no assumptions about the state of the ionosphere, or even its existence.

or
> groundwave loss and do my own calculations.

The only assumption EZNEC makes in its far field analysis about ground wave loss is that at an infinite distance it's infinite. The professional EZNEC programs, which do directly report far field ground wave signal strength when requested, use the Norton approximations (implemented in NEC) which are widely accepted.

Or I can follow up Eznec
> by using a program dedicated to either groundwave or ionospheric
> propagation.
>
> I agree preferences will differ. But it is important to understand

With that I agree wholeheartedly.

> Please do not take this note as any criticism of Eznec. It is a
> valuable (and free) calculating resource. But, as you demonstrate, it
> is difficult to describe in a few words exactly what it does.
>
> Please simplify!

First a note, EZNEC is not free. It's copyrighted, commercial software. Only the EZNEC demo program is free and can be copied and distributed freely.

Like other powerful tools, EZNEC requires some effort on the part of the user to understand its use. If you're not willing to make that effort, I suggest that you not use it, but find (or write) a program that suits you and your limited willingness to learn. [Give NEC-2 or MININEC a try!] All types of EZNEC, including the demo program, include a comprehensive and extensively indexed manual. I also recommend the ARRL

antenna modeling course, which numerous users have made positive comments about. But both of those are useful only to people who want more than to get a quick answer without taking any time to consider what the answer means.

I'll leave it to you and others to produce simple programs which do one specific, simple thing. There's a place for those, but also a place for more versatile programs like EZNEC which unavoidably require a bit more effort to fully use.

Wes' procedure calibrates both loss and phase, but my suspicion is
that it does not calculate a correct phase constant for longer lines.
The loss constant is probably simple, assuming a straight line between
the two cal points, but that is probably adequate for the task given
the object being measured.

>
>Of course, the short circuit measurement will give you the cable loss,

Agreed, that was someone else's suggestion, and if the line on the Smith Chart was a lossless arc rather than a lossy spiral, some more error creeps in, and the error is larger as VSWR increases.

I knocked up a small spreadsheet solution myself, it uses the gamma (with a small g) figure returned by my line loss calculator at a frequency, and the line length to calculate the impedance transformation. (Gee Excel is ugly with complex numbers.)

A more general solution would be one that calculates the fundamental RLGC model from k1, k2, vf, and Zo, and can calculate the impedance transformation as a function of Gamma and freq. I have a Perl library that I use for such things, but it won't port to Excel very easily. (If only Microsoft would extend Excel's capabilities instead of renaming and relocating functions from version to version.)

It highlights the convenience of a direct reading impedance meter! Still, I can see the advantages of the VVM over an impedance bridge, and they are both in a different class to the MFJ.

It may be "visible" but it is not a standalone signal like a TV aural
signal is. With an SCA signal there is more than one side band on the
main carrier involved. With TV aural there is not.

No next version. I've got an n2pk analyzer now. Much easier to use,
at least over its frequency range.

All good points and while not thinking too much about it (or at all really) the original problem was measuring the parameters of a loaded vertical. This sounds like a pretty narrowband problem. IF the line isn't too many wavelengths long and the frequency sweep isn't too wide, the phase rotation from one end of the frequency band to the other should be much less than one trip around the Smith chart and the loss variation should be minimal and for all intents linear.

Is it possible to get some fairly brief opinions without causing a war or even arguments ....
Is it likely to damage an Icom AH4 auto antenna tuner if the "antenna" terminal is attached to one leg of a V (resonant at 14Mhz) and the earth terminal is connected to the other leg of the V (resonant at 7Mhz) without any additional grounding. Is there any reason to swap the legs around. Assume 100 watts max. It would be helpful if any opinions came from those who are familiar with the internals of the AH4. It would also be helpful if any repondents understood that others could have a differing opinion. de VK2DQC, Allan. tnx

Both the 2006 ARRL Handbook and the 20th edition (2006) Antenna Handbook are
sitting in my book shelf.

These have been advertised in QST in the last 2 issues.
I get a flyer for availability of ARRL publications about 4 times a year
(membership perk?) Ordered mine via ARRL Store web site the 2nd week of
December.
All arrived 1 week before Christmas.

I want to put a short 2 meter yagi and a long 70cm yagi on the same vertical mast. The 70cm will be a horizontally polarized, center mounted 17' boom and the 2 meter will be a vertically polarized, end mounted 6 foot boom. How far apart do they need to be? I will only be transmitting with one at a time but one could be receiving and the other transmitting, the 70cm will be for ATV receive only for now.

---

uV/m = 10^[(dBm - G + 20*log(F) + L +75)/20]

where

dBm = signal level at receiver input in dB with respect to 1 mW
G = receiving antenna gain in dBd
L = line loss in decibels
F = Frequency in MHz

If you do a Google search for the AH-4 -- there used to be someone
with a page that showed it hooked up to a dipole, using the ground lug
for one of the dipole elements.

Is it a 48 ft. dipole off-center-fed 16 ft. from the end?
If so, what do you seek to gain by off-center-feeding it?

I have used similar setups in commercial service all over alaska.
We used SEA1612B Autotuners feeding twin Morad 2600 Loaded whips
in a dipole configuration. The only caviate that I would put out
is, that you might think about decoupling the Coax Feedline and
Power Leads by wrapping them in bifilar fashion on a suitable
torriod core. The above systems are still in use 15 years later,
and doing just fine on frequencies from 2.0 Mhz all the way up to
26 Mhz. the other thng that you must figure on, it that these type
of antenna tuners can't tune the 1/2 Wave Resonante Frequency of the
connected antenna. So, one must carefully consider just where the
1/2 Wavelength Resonance Point is, and place it in a portion of the
spectrum that your not going to want to transmit.

Hi Ron,

To answer your question - No.

For one its units do not balance. It is not finding ï¿½V/m it is simply
and incorrectly converting to ï¿½V. There is no meters to be found on
the right hand side of the equation. The 107, as has been pointed
out, is simply the number of dB below 1mW to a 1ï¿½V signal across 50
Ohms. Even here the formula is in error as the sign would be wrong
(the dBm must be presumptively loss expressed as a positive number).
To complicate it further is the artificially forced absolute value
which invalidates any Field Strength (sic) greater than one milliwatt.

You were right to be skeptical, it is nonsense.

Well, in case you have faulty coils inside the transmitter
- you may expirience something what one of my friends called
"microphoning" :) - their inductance may slightly change according
to the vibrations, which may lead to somewhat unruly behaviour
of the device.

Source record: 65776

Greetings Cecil, many thanks for your interest. (Hope you have a very exciting New Year riding around on your magnificent Harley)

The reasons for the particular configuration that I am playing with were originally clear but have become a little fuzzy over time. My aims are to make an antenna that is 1) transportable 2) light weight 3) ground independant 4) to be erected on a caravan in various caravan parks without upsetting everybody 5) quick to set up and pull down 6) gives me a few bands to play with 7) possibly even work to some degree !

After trying verticals, loops and dipoles I was ready to give up. Then I remembered a thing called a Vipole that was lying on the garage rafters. I paid hundreds of dollars for it but I could never make it work. It is a V with two lightweight fiberglass whips that each have an inductance coil half way along their length. They are marked 7Mhz (12' roughly) and 14Mhz (9'6" roughly). (((The original design stipulated that the whips feed into a Balun and then an UnUn transformer, and then use coax down to the rig))).

Anyway, I guessed that I could use the two lightweight whips - still in a Vee configuration. I decided to dump the Balun and the transformer and replace them with an auto tuner that I had lying around. So, now I have the first five criteria - all I have to do is make it ring on a few bands without smoke signals. So far it appears to receive well but I have serious doubts about its radiation properties (if any) - time will tell.

I beleive that this same note is made in the AH4 documentation, thanks for the reminder, I'll look back at this. I'll also consider your thoughts re decoupling. And thanks for the tip on the Google search. I have actually tried the search on Google but may have been too quick to give up. Will do it again.

Cheers and have a great New Year
Allan

Sorry, whilst looking into the rhs I overlooked the 10^x/20... the lhs is in uV/m... but the formula does assume an Antenna Factor of 0db/m (and 1Hz bandwidth if talking about power densities).

Trying to find the minimal correction to your formula to make it work:

Field Strength (uV/m) = 10 ^ ((107 + RxPwr + AF) / 20)

Where:
o RxPwr is in dBm
o AF (=FS/Vin) includes matching effects and is in dB (1/m) (or dB/m for short)
o same bandwidth applies to both sides for continuous spectra

For a matched antenna in a 50 ohm system under plane wave conditions:

AF=20*log(9.73/lambda/gain^0.5)

What you intend doing will connect the "ground" rail of you tuner to
one side of the antenna, and unless you take other steps, the "ground"
rail of the tuner will be connected to the radio chassis via the coax
outer and the control cable. Perhaps the radio will be connected to
ground directly or indirectly.

This is not a lot different to feeding a dipole without a balun
(whether by coax or open wire line).

You might be concerned about whether the likely RF common mode
currents will disrupt or damage the control interface at the radio or
tuner.

There have been lots of reports of people doing what you propose, some
choke common mode currents below the tuner, sometimes with separate
chokes on the coax and control cable, some choke common mode currents
above the tuner, sometimes providing a local ground to the tuner, and
some do nothing.

I favour a choke above the ground mounted tuner, and a local ground on
the tuner to help to reduce the rf currents flowing on the coax and
control cables into the shack. I have done this with open wire feed
above the tuner to the dipole feedpoint and it worked fine without
noticeable "RF in the shack" problems.

I note that SGC is now producing an auto-tuner with balanced output,
but have no experience of its performance.

The main issue that I see with these tuners is the difficulty of
diagnosing faults and identifying faulty components for replacement,
and it makes me think twice about investing in them.

OK, I think I've got it. Although the autotuner will probably
tune the system, the 20m element will probably be an inadequate
counterpoise on 40m and the 40m element may develop a lossy
self-resonance below 14 MHz. A 40 ft. dipole with the tuner
in the middle would probably outperform what you have in mind.
But that's just my opinion which is what you asked for. Don't
let me discourage you from experimenting.

Can anyone tell me where I can get a schematic of the probe for the HP 8405 Vector Voltmeter?

Thanks
Jerry

> Can anyone tell me where I can get a schematic of the probe for the HP
>8405 Vector Voltmeter?

It can be found in the scanned copy of the ops-and-service manual for the 8405, which is in the HP section of the Boat Anchor Manual Archive site and its mirror.

Look for the 8405_service_6.pdf manual. The quality isn't great (a somewhat fuzzy scan of the Army-depot version of the HP manual, partially optical-character-converted into DejaVu and then turned into PDF) but it's probably usable.

From what I've read (I just bought one of these and am starting the test-and-refurbish process) the matched diodes are the most vulnerable components in the probes. The original parts are HP house-numbered and I assume they're no longer available. Some people have substituted 1N5711 Schottky diodes (easily available), others suggest 1N270 (gold-doped RF germanium diodes, still available), one gent suggested the HP/Agilent 5082-2815 which seems to be a matched-quad set of 5082-2811 Schottky diodes. The latter are probably the most sensitive but I'm a bit concerned about their low breakdown voltage. The 1N5711s have a higher threshold voltage but are a lot more rugged, I expect... don't know if they'll perform as well at high frequencies as the originals (whatever they are) or the alternatives. Other high-speed, low-threshold diodes (e.g. those intended for RF mixer and detector applications) could probably be used. No matter what you use, hand-matching pairs or quads would probably be a good idea.

The P-channel JFET in the probe was reported by one writer to be a 2N3379 but I don't know if that's correct. Possibly something like a MMBF546x part might be substituted?

The input capacitor is also sometimes damaged by overvoltage, I gather, and may need to be replaced as well.

There's a guy on eBay who sells a probe-repair kit... 8 diodes, 2 FETs, and instructions on doing the repair.

Thanks Dave, I really appreciate your info about choosing the components
for these probes. I dont have the skills needed to build something like
this. I depend on being fed information from guys like you, and I
appreciate your input.
I did download a manual from BAMA. I thought I'd read it, but must have
missed the probe schematic.

Thanks again
Jerry

Source record: 65790

Dear Steve K9SL:
Assuming that you wish the installation to be performed with reasonable (or larger) safety factors, you need the services of a professional engineer licensed in your state who has experience with towers and tower foundations. He or she will need engineering data from the manufacturer of the tower and from the possible suppliers of the new bottom section. He or she will need to know if there are exceptional facts about your site. They include wind experience, soil type, and expected antenna loads.

"Real world experience with" your tower, I submit, is of little value to the goal of having the tower installed with reasonable safety factors. Almost anything for a tower "bottom" will "work" for a while.

In lieu of professional assistance, the advice of Mr. Ferrell is of value.

It sounds as if you do not need to use anywhere near the safety factor I used in a recent tower installation that is in a populated area that is not too far from a several story building. The building can cause extra wind pressure. The top many feet of soil was just fill. Severe damage and risk to life could result from a failure. The resulting foundation removed all of the soil down to a hard-pan, built up the base a little with manufactured and well compacted soil, and then used enough reinforced concrete to counter-balance the tower even if there had been no soil on the sides of the foundation. I do not use such extreme measures with towers out in the country and well away from houses or people. However, my experience is that the wind loads under those circumstances are significantly above those specified by building codes. The building codes seem not to assume open spaces.

Good luck. Mac (and a P.E.) N8TT

5347. 2nd Floor grounding

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-31 15:16:19 UTC
From: jawod <jawod@fuse.net>
Message-ID: <d7b53$43b6a0c4$42a1bfc2$17580@FUSE.NET>
Source record: 65794

After reading the archive regarding 2nd floor grounding, a couple of questions.

Outside of sufficiently thick gauge wire and proper depth to grounding rod. Are there any ELECTRICAL (nonRF) issues left to resolve for a 2nd floor ground?

Several articles referred to long grounding lines being close to 1/4 wavelength as being a problem. Is this eliminated with balanced feedline?

Thanks,

john

Jerry,

I have just completed bringing an 8405a back on line. The BAMA copy is mostly readable and certainly useable. My unit had a bad probe and a bad pulse amplifier. Otherwise it aligned very well.

The probes are managable to work. I ended up buying an .024 PC bit to clean the solder holes. This allowed placing the diodes directly and then soldering them.

The detected phase angle appears to be dependent on having a matched sampling efficiency between the probes. This is certainly level sensitive and may be frequency dependent. I have tried several diodes including the origenal HP diodes.

I use a DVM to measure diode forward voltage drop. The origenal diodes measure about 390 mv. NTE584s measure about 420 mv and can be tuned to match at about 98%. This in practice is usable. 1n5711s measured about 440 mv and can be tuned to match to about 90%. The instrument will appear work but the phase angles are incorrect due to the sampling errors. I am still looking for a better choice then the NTE584s.

Let us know what you find out. - Dan

~~~~~~

No. You can not "ground" your station for RF, at least not in the
sense of running a wire to ground. Don't bother because it isn't
necessary anyway. You do need two kinds of ground, one for the AC
mains for safety, and one for lightning.

RF energy is expensive to generate. Don't waste it by running part of
it into a lossy "ground". Keep it up in the air where it belongs.
Baluns are your friend.

1) Make sure you have a good connection from equipment cases to AC Power main ground/earth. I use a 1/2 inch copper pipe on the table where my station is mounted. Each piece of equipment on the table, transceivers, amplifiers, power supplies, computer, are individually bonded to this copper pipe. This 1/2 inch copper pipe is then connected to earth ground by a #6 AWG wire run directly to the electrical service panel where it is connected to the earth connection.

2) If you use a 1/4 wavelength, or equivalent, vertical antenna you need a counterpoise, often called 'ground', at the base of the antenna.

3) A balanced feedline is used for a balanced antenna, e.g. dipole etc., to minimize RF coupling to the transmission line. The balanced line needs to run away from the antenna for a minimum of 1/4 wavelength at right angles to be effective. A dipole fed with coax cable needs a balun to produce a balanced signal to the antenna. The coax should also run away from the antenna at right angles for 1/4 wavelength to be effective in minimizin current on the coax. If you need to run from the antenna at less than 1/4 wavelength then a series of chokes or ferrites should be used to keep RF out of the house. These chokes/ferrites should be mounted at least 1/4 wavelength from the antenna.

A symmetrical feedline is no guarantee of balance. Balance is achieved only when the two conductors carry equal and opposite currents, and that can be achieved with either coax or symmetrical feedline. Likewise, imbalance can occur with either type of feedline. You can learn more about the issue at http://eznec.com/Amateur/Articles/Baluns.pdf. That article doesn't mention imbalance caused by coupling to the antenna, which can occur if a dipole isn't symmetrical or if either type of feedline is asymmetrically placed relative to the antenna.

Hi Jim,

I would have to disagree with that. Field Strength is naturally
assumed to be a constituent of Free Space, or at least in a path
largely defined with an impedance of 120 ï¿½ pi Ohms. Volts and Current
are convertible through this. dBm is likewise related to an
impedance. It is classically 50, 75, 200, 600, or 1000 Ohms depending
upon industry usage. Without this understanding (often implicit
within those industrial applications) the comparisons of dBm citations
would become quite strained (for instance, computing gain/loss).

If posed this same query of translating dBm to Field Strength, I would
presume the underlying basis of comparison would be that same 120 ï¿½ pi
Ohms. This is hardly a stretch given Field Strength can also be
described in units of power and area. The proper usage in Field
Strength context would be
dB(re 1mW/mï¿½)
where dBm is frequently a short-hand for
dB(re 1mW into 600 Ohms)
or
dBm(600)
where, perhaps the user actually meant
dBm(50)
Hence, a bald citation of dBm carries a lot of implicit baggage.

Suffice it to say that there are a world of dB conventions for
expressing relationships.

The simple lesson learned from the original question is that when both
sides of the equation do not balance in their units; then that
equation is incorrect. There were more errors than that, but the lack
of balance was sufficient to condemn its usage.

Hi Dan
I picked the 8405 out of a dumpster at a mil surplus place. Actually I
picked out two HP 8405A Vector Voltmeters. One is complete. The other had
one of its probes severed and I couldnt find that probe. I will try to
build two probes on boards with a BNC in place of the pointed probe.
I dont anticipate being able to make this Voltmeter an accurate
instrument. So, I wont be able to offer any data that anyone else would
want.

~~~~~~

Nonsense.

An unbalanced antenna and/or feedline can be VERY effective. Hams have
used them since the days of spark. All the unbalance does is change
the antenna pattern, not the effectiveness. It will be better in some
directions, worse in others.

I have a dualbander with a magmount stuck to the rig itself. It works
just fine.

Yes Cecil, it is a "billy cart" antenna, and I guess that lots of antenna would outperform it - but I have to keep it within the criteria:
1) transportable 2) light weight 3) ground independant 4) to be erected on a caravan in various caravan parks without upsetting everybody 5) quick to set up and pull down 6) gives me a few bands to play with 7) possibly even work to some degree :-)
I will take Owen Duffy's advice to reduce RF getting back to "the caravan shack", then continue to experiment. At this stage it seems to receive very well, but waiting to get answers to my CQDX.

73 de VK2DQC "portable anywhere in Aus."

The ARRL Antenna Book goes through a major revision every few years.
The 20th Edition is the current edition. I have every edition of the
Antenna Book and each has a unique presentation of enough of its
material to warrant the purchase, IMHO.

ARRL does some degree of revision to the Handbook every year, with the
2006 being a pretty heavy revision. What I suggest hams do is to watch
the ads and note which chapters were given major revisions. When you
see chapters whose subject topic interests you, it is probably worth
buying the Handbook that year.

Ed
